THERE are yet some strange forms of nervous disorder which require to be mentioned; but upon which I do not intend to dwell. *Catalepsy* is one of these; and what is called *ecstasy* another. These affections are very rare as well as very wonderful: so wonderful and rare, that weak and superstitious persons have referred them to the interposition of supernatural agents in human affairs; and stronger-minded persons, who happen never to have witnessed such diseases, deny their occurrence as fabulous, or laugh at them as the tricks and cheatings of imposture. They certainly do happen, however; and they happen mostly in the same class of persons in whom hysterical and nervous complaints of all kinds are most common. They often appear to be produced by similar causes with these: they resemble hysteria in being seldom attended with any danger to life: their pathology is, if possible, still more obscure than that of hysteria: and if I were to speak of the treatment which would seem to be most suitable for their cure or prevention, I should merely have to repeat what I said, upon the treatment and prevention of hysteria, in yesterday's lecture. I shall content myself, therefore, with a short description of these two affections, that you may be aware of their characteristic phenomena, and not be taken by surprise in case either of them should occur to you in your practice.

A fit of catalepsy implies a sudden suspension of thought, of sensibility, and of voluntary motion; the patient remaining, during the paroxysm, in the position in which she (for it is almost always a female) happened to be at the instant of the attack, or in the position in which she may be placed during its continuance; and all this without any notable affection of the functions of organic life.

This is certainly a very curious state, and one different from any that we have yet contemplated. We have had the muscles rigidly contracted with tonic spasm, while the powers of the mind, and the sensibility of the body, were unimpaired. We have had the same muscles shaken with clonic convulsions; both with and without coexistent disorder of the intellectual functions. But here we have a new phenomenon: the mental faculties are in abeyance, and the sensibility is abolished, and so also is the function of voluntary motion; but the limbs are not tied down by spasm: nor agitated by successive contraction and relaxation of their muscles; nor yet left, like portions of dead matter, passively obedient to the laws of gravity: they assume any posture in which they may be placed, and that posture, however absurd, however (to all appearance) inconvenient and fatiguing, they retain, until some new force from without is applied to them, or until the paroxysm is at an end. The patient so affected, with open staring eyes often, and outstretched limbs, looks like a waxen figure; or an inanimate statue; or a frozen corpse. Indeed, Hoffman seems to have formed the strange

conclusion that, as catalepsy, so far as he knew, occurred most frequently in winter, it must depend on congelation of the nervous fluid.

These singular attacks occur in paroxysms; and they have been known to alternate with well-marked hysteria; and to take place in connexion with insanity. I have never seen an instance of perfect catalepsy, which I now regret, as I once had an opportunity of doing so, of which I did not avail myself. Dr. Gooch has described a case of it, as he witnessed the disease in a patient who suffered puerperal mania. She had long been subject to the common forms of hysteria. This is illustrative of what I have often stated respecting the consanguinity of these nervous disorders. It had become necessary to confine this patient in a strait-waistcoat; she was attended by Dr. Gooch and Dr. Sutherland. I will quote Dr. Gooch's account of the cataleptic state, for it is authentic and modern. He says, "A few days after our first visit we were summoned to observe a remarkable change in her symptoms: the attendants said she was dying or in a trance. She was lying in bed, motionless, and apparently senseless. It had been said that the pupils were dilated, and motionless, and some apprehensions of effusion on the brain had been entertained; but on coming to examine them closely, it was found that they readily contracted when the light fell upon them; her eyes were open, but no rising of the chest, no movements of the nostrils, no appearance of respiration, could be seen; the only signs of life were her warmth and pulse; the latter was, as we had hitherto observed it, weak, and about 120.

"The trunk of the body was now lifted, so as to form rather an obtuse angle with the limbs (a most uncomfortable posture); and there left with nothing to support it; there she continued sitting while we were asking questions and conversing; so that many minutes must have passed. One arm was now raised, then the other; and where they were left, there they remained. It was now a curious sight to see her, sitting up in bed, her eyes open, staring lifelessly, her arms outstretched, yet without any visible sign of animation. She was very thin and pallid, and looked like a corpse that had been propped up, and had stiffened in this attitude. We now took her out of bed, placed her upright, and endeavoured to rouse her by calling loudly in her ears; but in vain. She stood up, but as inanimate as a statue. The slightest push put her off her balance. No exertion was made to regain it. She would have fallen if I had not caught her.

"She went into this state three several times. The first time it lasted fourteen hours, the second time twelve hours, and the third time nine hours; with waking intervals of two days after the first fit, and one day after the second. After this the disease resumed the ordinary form of melancholia; and three months from the time of her delivery she was well enough to resume her domestic duties."

There is a minor form of this affection described, in which the patient is incapable of moving or speaking, but is conscious of all that goes on around him at the time. I saw a lady last year, who was subject to these attacks of imperfect catalepsy: which have been whimsically, but very expressively, called also attacks of *daymare*. From her time of life, her habits, and some other points in the history of the disease, I concluded that in her case these seizures, of temporary loss of muscular power without loss of consciousness, were dependent upon a diseased state of the blood-vessels of the brain. She afterwards consulted Dr. Chambers; and he told me that he had formed the same opinion of the nature and cause of the symptoms.

In what is called *ecstasy*, the state is different. The patient is lost to all external impressions; but wrapt and absorbed in some object of the imagination. The muscles are sometimes relaxed; sometimes rigid as in slight *tétanus*; but the loss of voluntary power over them is not complete or universal, for these patients often speak in a very earnest manner, or sing. They are, as the term *extasis* imports, out of the body at the time, wholly engrossed in some high contemplation. This state is not uncommon as forming a part of religious insanity; and sometimes it runs into ordinary hysteria. Nervous and susceptible persons are apt to be thrown into these trances under the influence, whatever it be, of mesmerism: and grave authors assure us that the intelligence which then deserts the brain, concentrates itself in the epigastrium; or at the tips of the fingers: that people in that state read letters which are placed upon their stomach, or applied to the soles of their feet; answer, oracularly, enigmatical questions; discover and declare their own and other persons' internal organs

diseases; describe minutely and accurately distant scenes which they have never visited, nor previously heard of; and even foretell future events. *Credat Judæus Apella, non ego.* I take for granted that they who were in the habit of speaking, a few years since, in some of our places of worship, in what they called *unknown tongues*, were either gross impostors, who deserved to be publicly whipped, or persons labouring under this disease, and wanting physic. Dr. Copland mentions a curious fact in connexion with this subject. He says that many of the Italian Improvisatori are in possession of their peculiar faculty only while they are in a state of ecstatic trance; and that few of them enjoy good health, or consider their gift as otherwise than something morbid.

Do not suppose, from what I have just said, that I ignore the glaring *facts* of mesmerism. I have seen and scrutinized too many of them to doubt their genuineness, or to ascribe them to mere imposture or collusion. You may desire to know, and you have a right to know, my creed upon this vexed and much-abused subject. It is this. Of the brain and nerves there are many and various strange conditions, which we reckon as manifestations of disease or disorder. They occur, as it would seem, spontaneously; or during the progress of some better known malady. I have given you several wonderful examples of such unnatural and morbid states under the heads of hysteria, chorea, catalepsy, ecstasy, trance. I might have described to you the curious condition, or alternating conditions, of *double-consciousness*; and the familiar phenomenon of *sleep-walking*. Now, whatever condition of this kind may arise thus spontaneously, may also, I believe, be produced, in some persons, under the mesmeric practisings. Not however through any material or occult influence emanating from the mesmeriser; but subjectively, from the mental attitude (if I may use that expression) in which the person mesmerised is led to place himself. There are many simpler forms of unconscious mesmerism, which we witness every day, without regarding or recognising them: the propagation of a yawn for example; the irresistible slumber under the drone of a dull preacher. Into these moods or postures of the mind, into this discord of the nervous functions, this disturbance of their natural harmony or equilibrium, the mesmeriser may beguile his victim: but the experiments of Mr. Braid show clearly that the agency of the mesmerist is not essential to the manifested effect. Any one, having the requisite susceptibility, may put himself into the mesmeric sleep or the mesmeric trance, by fixing his eyes and his attention steadily and unremittingly upon an object made to project a little way from the centre of his own forehead. The phenomena are subjective phenomena. The determining influence is from within as much as, or even more than, from without. Derangements such as sometimes occur thus in disease, may also sometimes occur under the mesmeric atmosphere: but no other or more mysterious derangements. Thus much I perfectly believe. I believe too that sleep may sometimes be conciliated by the monotonous biddings of mesmerism, when drugs might fail to procure it: and that such sleep may become sometimes, and in certain diseases, a mode and an instrument of cure. But I go no further. All the transcendental phenomena—the miraculous diagnoses and revelations, the clairvoyance, the prophecies—I class with the spirit-rappings and the table-turnings, as evidences of imposture on the one side and of miserable credulity on the other, and as alike scandalous in an age and country which vaunt themselves to be enlightened.

Leaving these nervous disorders, in which the function of voluntary motion is so curiously modified; and in which there sometimes is no alteration of the intellectual faculties, and sometimes very great disturbance, or the complete suspension of them; I would beg to turn your attention to another class of complaints, in which the nervous system is still the part principally interested, but in which the deviation from the natural state is manifested chiefly in the function of *sensation*: the powers of thought and of voluntary motion being scarcely affected, or not affected at all. Complaints, I mean, in which the sensibility is perverted, and augmented; cases of nervous *pain*. We have considered before that modification of sensation which consists in numbness, or anæsthesia, *i. e.* in the diminution of the natural sensibility, or its total privation. We have noticed also incidentally many perversions of sensation; such as giddiness, nausea, faintness, and the like; and in the same incidental way the morbid *exaltation* of the sensibility, which is called *pain*, has come before us, as a

symptom of various other diseases; of inflammation, and of hysteria. But there are diseases which consist of pain, and of nothing else, that we can perceive. They are often attended by no inflammation, no detectable change of structure in the painful part, no fever. These affections are included under the general term, *neuralgia*. Now pain is one of the things which we are oftenest consulted about; and these neuralgic pains are apt to be excessively severe and troublesome; and it cannot but be of importance to understand what has been ascertained of their nature, and causes, and capability of cure.

That pain is owing to some morbid condition or to some irritation of a particular nerve, we may sometimes know, by finding that it is felt exactly in the course, and follows the distribution, of that nerve. But when, as often happens, the pain is confined to a certain spot, we then conclude it to be neuralgic, if and because we can find no other explanation of its existence.

What increases the difficulty of making out the cause and origin of these nervous pains, is that they may be produced by some source of irritation operating at a distance from the part in which the pain is felt. It may be placed in the brain itself, or in the spinal cord; or in the trunk of the nerve that supplies the affected part; or in one of the branches of the same trunk, which branch is distributed to another part. If you strike the inside of the elbow in a certain way, so that the blow lights upon the ulnar nerve, a peculiar tingling sensation is felt in the little finger: that is, *not* in the part struck, but in the sentient extremity of the same nerve; and the same thing happens continually in disease. There is an excellent paper on this subject, by Sir Benjamin Brodie, published in one of the earlier volumes of the *Medical Gazette*, in which he has collected numerous and striking illustrations of the production of nervous pain by irritation situated in a distant part. Thus, to take a case in point; a man was admitted into St. George's Hospital on account of severe pain on the inner side of his knee. The joint was carefully examined, but no mark of disease could be detected in it. On tracing the limb upwards, however, an aneurism of the femoral artery, as big as an orange, was discovered in the thigh. This the patient thought nothing of; his only concern was the pain in his knee. Sir E. Home performed the usual operation for aneurism: and the moment the ligature was drawn firmly round the artery in the upper part of the thigh, the tumour ceased to pulsate, and the pain in the knee ceased also. This man died four or five days after the operation; and upon inspection of the limb after his death, the aneurism was found reduced to one-half its former size; and some branches of the anterior crural nerve, which passed over it, and which must have been kept on the stretch previously to the operation, were seen to terminate in the part to which the pain had been referred on the inside of the knee. There is just such another case related by Dr. Denmark, in the *Medico-Chirurgical Transactions*. A sailor was wounded by a musket-ball in the arm. The wound healed; but the patient remained affected with agonizing pain, beginning in the extremities of the thumb and fingers, except the little finger, and extending up the fore-arm. His sufferings were so great that he willingly submitted to have the limb amputated: and the operation gave him complete and immediate relief. When the severed limb was dissected, a small portion of lead, which seemed to have been detached from the ball when it struck against the bone, was found imbedded in the fibres of the median nerve.

These examples teach us, when we receive complaints of pain in any part, and can discover no cause of pain in the part itself, to look for some possible source of irritation in the trunk of the nerve, from which the part in question is supplied with nervous fibrils.

But the source of irritation may be further back than this: it may depend upon a diseased state of the spinal marrow, or of the brain. Of this, having had so many examples before us already, I need not seek for any new illustrations.

Sometimes, again, irritation applied in the course, or at the extremity of *one* branch of a nerve, will give rise to pain at the extremity of *another* branch of the same nerve. The sensation appears to be reflected, as it were, along the branch which is not directly the subject of the irritation. Thus filaments of the phrenic nerve penetrate the diaphragm and communicate with the ganglia that lie around the celiac artery; other filaments are distributed to some of the muscles about the shoulder;

and in this way has been explained the well-known fact, that disease or irritation of the liver is very apt to be accompanied with pain in the shoulder.

Thus also we have pain in the glans penis, from irritation of the bladder, produced by a stone there: pain of the thigh and testicle, from irritation of the kidney: pain of the left arm, from disease of the heart: pain in the feet, from stricture and irritation of the urethra.

There are many pains also, plainly enough connected with irritation of distant parts, although no other nervous connexion can be traced between the parts, except that which is afforded by the nervous centres. In such cases we must suppose that the morbid impression travels to the brain, and then the sensation is referred to the part affected through another nervous channel of communication. Dr. Wollaston was accustomed to relate the following story of himself. He had eaten some ice-cream after dinner one day; and his stomach did not seem to be capable of digesting it. Some time afterwards, when he had left the dinner table for the drawing room, he found himself rendered lame by a violent pain in one ankle. Suddenly he became sick, the ice-cream was vomited, and instantaneous relief of the pain followed its ejection from the stomach. "A gentleman (says Sir Benjamin Brodie) awoke in the middle of the night, labouring under a severe pain in one foot. At the same time certain other sensations, to which he was not unaccustomed, indicated the existence of an unusual quantity of acid in the stomach. To relieve the latter he swallowed a large dose of alkaline medicine. Immediately on the acid in the stomach having thus been neutralized, the pain in the foot left him."

The lesson that we learn from all these facts is this: that when we can find no explanation of a pain in the very spot in which it is felt, we should look for some condition that may explain it, in the trunk of the nerve supplying that part; or in the parts supplied by other branches of the same nerve; or (if still we are unsuccessful), we seek for other indications of disease in the brain or spinal marrow: and if these be wanting, we should extend our search, and inquire whether there be any intelligible disorder or cause of irritation elsewhere, which, operating through the medium of the nervous centres, may have occasioned the sympathetic pain of which our patient complains.

I say we should institute this quest, because, if it be successful, it may teach us, on the one hand, that the cause of the pain is fixed and irremediable; or, on the other, it may enable us by some simple and obvious expedient to cure the pain. But sometimes we shall be quite disappointed in all this seeking. We shall find nothing, either in the living patient, or in the dead body, which throws the smallest light upon the cause of the neuralgia.

Now with respect to those neuralgic pains, for which we can discover no adequate cause, either in any diseased structure, or in any morbid action of the blood-vessels, there are certain general facts observable which I will mention before I specify any particular forms of neuralgia. They occur in all parts of the body; but they are more frequent about the head than in any other part; and next of all, probably, in the abdomen. In the head, or face, the branches of the fifth pair of nerves are very frequently the seat of neuralgia; and to such pain, in that situation, the name of *tic douloureux* is generally given. The painful affection called *hemicrania* is another example of neuralgia of the head. Certain forms of *angina pectoris*, and of *gastrodynia*, seem to belong to the same class of disorders: and *sciatica* — which depends on different causes in different cases — is often rather a neuralgic than a rheumatic pain. I have stated that the pains sometimes follow the track of certain nerves; but this is not, I think, very common. Inflammation of the nerve, or of its investments, generally causes pain having that property; but the truly nervous pains are much better characterized by the suddenness with which they come on, and the suddenness with which they sometimes go off also; by their intermittence in many cases, and the regularity of the period at which they often, though not always, return; by the total absence (in most cases) of heat and swelling, and often of tenderness too, when they are external, and of febrile symptoms when they are internal, even although their intensity be extreme; by their apparent dependence, in numerous instances, upon sudden changes of the weather; by their occurring chiefly in persons of a nervous temperament in whom the health is otherwise disordered; and by their frequently abating under tonic remedies, or what are called specifics, rather than under anti-

phlogistic treatment. (ALISON's *Outlines*.) There is another circumstance, characteristic of these pains, which has been mentioned by Sir Benjamin Brodie, and I do not know that the same thing has been noticed by other writers. These pains are often suspended by sleep. "A person suffering from tic douloureux in the face may for a time be prevented from falling asleep, but if once asleep, his sleep is likely to be sound and uninterrupted for many hours." He says that though there may be exceptions to this rule, they are comparatively rare. Now this, you will observe, is quite analogous to what takes place in certain spasmodic affections of the muscles also. The jactitations of chorea are almost always suspended during sleep. It is the same with the spasmodic wry neck, in which the involuntary contraction of some muscle, commonly the sterno-cleido-mastoideus, drags the chin round, and the head awry. Persons affected with that sort of deformity when awake, have their necks flexible enough, I believe, while they are sleeping.

I mentioned just now one character of these neuralgic pains, viz., the total absence in most cases, when they occupy the surface, of heat, redness, swelling, or tenderness; and I said *in most cases*, because there are unquestionably exceptions to this. After these pains have been long-continued and intense, they may give rise even to a moderate degree of inflammation of the part: which may become tender to the touch, manifestly vascular, and even swollen a little. "In a gentleman," mentioned by Sir B. Brodie, "who suffered for a great length of time what was regarded as a most severe tic douloureux in the face, at first the parts to which the pain was referred retained their natural appearance, but ultimately they became swollen, from an effusion of serum into the cellular texture, and so exquisitely tender that they could not bear the slightest touch. In a patient who had laboured for some time under pain in the testicle, depending on a calculus passing down the ureter into the bladder, the testicle became tender and considerably swelled."

The attacks of neuralgia may recur at intervals of a few seconds only; or they may take place daily, or every other day; or they may be separated by much longer intervals, regular or irregular. Sometimes there is continual pain, but it is wonderfully exalted and aggravated by fits. It is described as being sharp, sudden, twingeing, like an electric shock in its momentary duration. Sometimes it is attended by a feeling of constriction and cramp, although no muscular contraction accompanies it. I suppose that is one reason why such pain is so often spoken of even by medical men, and almost always by the vulgar, as *spasm*. Whenever a patient tells me he has spasms here or there, I am obliged to request that he will explain himself further. I want to know how he construes spasm; and nine times out of ten I find that he intends a sudden and sharpish, and generally a transitory attack of *pain*: whereas the term spasm really signifies, and ought to be restricted to, involuntary muscular contractions. When a medical man prints a case in which he states that spasms occurred in such or such a part, it is impossible to tell what he means, unless that term is explained by the context. Pray avoid this inexactness.

The most common of these neuralgic pains, as I have said, is that which has been called *κατ' ἑξοχήν*, *tic douloureux*, and which is situated in the facial branches of the fifth pair of nerves; nerves, as you know, of sensation; and it is usually restricted to one of the three branches that emerge severally to supply the parts in their neighbourhood. Sometimes two, sometimes all of them, are implicated. The middle one of these branches, the infra-orbitary, is, I believe, the most commonly affected in the severer forms of the complaint. The torture occasioned by this dreadful malady is sometimes excessive. The sufferers speak of it as anguish that is scarcely endurable; and you see, in their quivering features and restless limbs, that the acute bodily pang is, indeed, hard to bear.

When the uppermost branch of the trifacial nerve is the seat of the complaint, the pain generally shoots from the spot where the nerve issues through the superciliary hole; and it involves the parts adjacent, upon which the fibrils of the nerve are distributed; the forehead, the brow, the upper lid, sometimes the eyeball itself. The eye is usually closed during the paroxysm, and the skin of the forehead on that side corrugated. The neighbouring arterics throb, and a copious gush of tears takes place. In some instances the eye becomes blood-shot at each attack; and when the attacks are frequently repeated, this injection of the conjunctiva may become permanent.

When the pain depends upon a morbid condition, or morbid action, of the middle

branch of the nerve, it is sometimes quite sudden in its accession, and sometimes comes on rather more gradually; being preceded by a tickling or pricking sensation of the cheek, and by twitches of the lower eyelid. These symptoms are shortly followed by pain at the infra-orbitary foramen, spreading in severe flashes (so to speak) over the cheek, affecting the lower eyelid, ala nasi, and upper lip, and often terminating abruptly at the mesial line of the face. Sometimes it extends to the teeth, the antrum, the hard and soft palate, and even to the base of the tongue, and induces spasmodic contractions of the neighbouring muscles.

When the pain is referrible to the inferior or maxillary branch of the fifth pair of nerves, it darts from the mental foramen, radiating to the lips, the alveolar processes, the teeth, the chin, and to the side of the tongue. It often stops exactly at the symphysis of the chin. Frequently it extends in the other direction to the whole cheek and to the ear. During the paroxysm the features are liable to be distorted by spasmodic action of the muscles of the face, amounting sometimes to tetanic rigidity, and holding the jaw fixed and immovable.

The paroxysms of suffering in this frightful disease are apt to be brought on by apparently trivial causes; by a slight touch, by a current of air blowing upon the face, by a sudden jar or shake of the bed in which the patient is lying, by a knock at the door, or even by directing the patient's attention to his malady by speaking of it, and asking him questions about it. This was remarkably manifest in a patient who came into the hospital under my care for another complaint; but who had for some time been subject to tic douloureux. The necessary movements of the face in speaking, or eating, are often sufficient to provoke or renew the paroxysm. At the same time firm pressure made upon the painful part frequently gives relief, and causes a sense of numbness to take the place of the previous agony.

This cruel malady occurs most commonly in persons who exhibit, in other respects, the signs of an unsound, or deranged, or debilitated system. It is more apt to fasten upon those who are pale, and asthenic, and upon individuals whose powers have been broken by advancing years. It is not unfrequently attended with some obvious disorder of the digestive organs, and ceases or is mitigated when that disorder is corrected. Sometimes it is clearly connected with a disposition to rheumatic affections; coming on in persons who suffer rheumatism in other parts, and even alternating with rheumatism in other textures. It is observed to be common among fishermen, and the inhabitants of marshy districts; and in some of these sufferers it may be attributable to their habitual exposure to cold and moisture. The trifacial nerve, lying superficially, and being unprotected by any artificial covering, is more likely, perhaps, for that reason, to be affected by vicissitudes of temperature; but in many of these cases the disease seems to be produced by the *malaria* which is prevalent in those situations. The paroxysms are then not only intermittent, but periodical, and they will frequently yield to the remedies which have been ascertained to be specific against ague and its various modifications. Sometimes the facial neuralgia is evidently dependent upon some general state of the system: for it will cease in the face, and fix itself in some other place; and in this way it may come to occupy several distant parts of the body in succession. There are other cases again in which the disease has a local origin, and results from some diseased bone, or exostosis, in the neighbourhood of the painful spot. The late Dr. Pemberton afforded a well-known example of this. He was seized with tic douloureux when in the very zenith of his reputation, and in the fullest exercise of his profession in this town. It completely ruined him: compelled him to give up business. He ultimately died of apoplexy. When his head was examined after death, the os frontis was found to be unusually thick, and on the falciform process of the dura mater, at a little distance from the crista galli, a small osseous substance was discovered, nearly half an inch long, and almost as broad. Sir Henry Hallford has recorded several other instances in which the disease was connected with some morbid condition of the bones of the head or face.

Now tic douloureux is one of those complaints for the cure of which there exists a number of specific remedies. But what I have been stating of this disease will suffice to convince you that, as it depends upon different causes in different persons, it is absurd to expect that any single drug—or even any one plan of treatment—will always remove it. Our first care, in every example of it that comes before us, must be to investigate all the particulars of the case. We must not be satisfied with

learning that the complaint is tic douloureux, and then go on prescribing one after another the reputed specifics for tic douloureux. It may happen that the origin of the disease is plain, and the remedy obvious. We must endeavour to make out whatever is amiss in the system at large, or in the state of particular functions. Very rarely, I believe, tic douloureux is dependent upon a condition of general plethora. Mr. John Scott gives the case of a gentleman who suffered severely from it for some time; at length he had an attack of apoplexy, and for this last disorder he was copiously bled, and the bleeding seemed to cure the neuralgia. Much more frequently we find evidence of a feeble or a shattered state of the system; debility and paleness; and then we may expect to do good by the treatment so strongly recommended by Mr. Hutchinson, viz., by giving the carbonate of iron. This remedy has been put largely to the test, since Mr. Hutchinson wrote in commendation of it, by Dr. Elliotson, and subsequently by others. Dr. Elliotson states it as the result of his experience that, "in all cases of neuralgia, whether exquisite or not, unaccompanied by inflammation, or evident existing cause, iron is the best remedy." I have already explained the manner of administering the carbonate of iron, the quantity in which it may be given, and the limits within which I should be inclined to restrict the doses. Sir Benjamin Brodie thinks it probable that the carbonate of iron proves beneficial by its mechanical operation on the internal surface of the intestines: but I should rather ascribe its good effect to the well-known property of preparations of iron, of giving firmness to the nervous system; apparently by increasing the quantity of red corpuscles in the circulating blood. However, it is of the utmost consequence that the state of the digestive organs should be attended to. Mr. Abernethy used to relate, in his lectures, many instances of tic which he had succeeded in curing by measures which were solely directed to the improvement of the stomach and bowels. He had a notion, that in patients who suffer under this disorder, there were always two functions wrong; those of the nervous system on the one hand, those of the digestive system on the other. And I am sure you will commonly find indications of a faulty state of both these systems. "The two," he used to say, "were the common parents of a numerous progeny of very dissimilar local diseases. In tic douloureux, you must seek to put the digestive organs right, or to soothe the nervous system, according as the one or the other may seem to be the principal and primary cause of the disease. Take away one of the parents, and there will be no more propagation."

In these cases, the unhealthy state of the digestive apparatus may be marked by obvious signs: a furred tongue, loss of appetite, costive bowels: or it may reveal itself by no other symptom than the pain. It may depend upon the mere presence of acid in the stomach. Dr. Rigby tells us that having suffered in his own person an intense attack of tic douloureux, which opium did not assuage, he swallowed, at the suggestion of a friend, some carbonate of soda dissolved in water. The effect was almost immediate: carbonic acid was eructed, and the pain quickly abated. More often the cause of offence appears to lie in some part of the intestines; and purgatives do good. Sir Charles Bell—drawing a bow at a venture—achieved the cure of a patient, upon whom much previous treatment had been expended in vain, by some pills composed of cathartic extract, croton oil, and galbanum. He mixes one or two drops of the oleum tiglli, with a drach of the compound extract of colocynth; and gives five grains of this mass, with ten grains of the compound galbanum pill, at bedtime. I mention the exact proportions and dose, because other cases have been since reported, both by Sir Charles and by others, in which the same prescription was followed by the same success.

When the disease occurs in a rheumatic individual, and especially when, as is sometimes the case, it alternates with rheumatism of other tissues, the remedies which have been found useful in rheumatism deserve a fair trial: guaiacum; colchicum; calomel and opium; iodide of potassium.

When all has been done that can be done towards restoring or improving the general health, we may turn our thoughts to local remedies. It is plain that these must be inefficient when the local pain results from constitutional causes that are undressed, or perhaps incurable. Yet even then topical measures may soothe the pain for a while.

One of these topical expedients, which promised well when first thought of, is the division of the trunk of the painful nerve, so as to cut off the nervous communication,

through that main channel at least, between the painful part and the brain. This was originally proposed by Dr. Haighton, and was at first attended with some little success; but in a great number of instances it has signally failed, as indeed might have been expected. In Dr. Pemberton's case the several branches of the fifth pair were cut by Sir Astley Cooper: but in vain. When there is any reason to think that the disease has a constitutional origin, or a local *distant* origin, the division, or even the excision, of a part of the nerve must be perfectly useless. It would be as reasonable (as Mr. Abernethy has observed) to expect to cure gout by cutting the nerve that goes to the great toe: or to perform castration with the view of remedying that pain in the testicle which is apt to be produced by the passage of a calculus through the ureter. Nevertheless there are cases, in which the division of the nerve, or some other surgical operation, is required. If you can make out that there is any tumour pressing upon or adherent to some part of the nerve—or if some foreign body, as a splinter or a shot, should be ascertained to be in contact with the surface of the nerve, or to be entangled in its substance—the tumour or the foreign body may be removed by the knife, with the strong expectation that a cure will be thus effected. And if this cannot be done, or if the nerve itself be altered in structure, either from disease or injury, (I am referring now to neuralgia in general, and not merely to that in which the facial branches of the fifth pair of nerves are implicated,) under those circumstances it will become a very proper subject of deliberation whether the nerve should be divided, or the limb amputated.

In the *Medical and Physical Journal* there is a case described by Mr. Jeffries, of a violent facial neuralgia, cured by the removal of a small fragment of china, which had been lodging in the cheek for fourteen years. And Mr. Desoot mentions an instance in which a very severe affection, of ten years' standing, was removed by the abstraction of a carious tooth. I saw, not many days ago, a young woman whose finger had been amputated for very acute neuralgic pain which she had suffered in it; and the amputation had been successful in liberating her from that pain.

Sometimes we may hope to afford relief to the suffering patient by means which tend to remove or lessen the *exciting* cause of the paroxysms. Of this I may mention one remarkable example, which fell in part under my own observation: although I had nothing to do with the treatment. I was asked, a few years ago, by an acquaintance, to go with him to call upon a relation of his, who laboured, he said, under tic douloureux: he did not wish me to see her professionally, but was desirous that I should witness what he considered an extraordinary complaint. I saw a young girl, about twelve or thirteen years old, very pale and delicate, lying on a sofa; and I learned from her and from her mother that she was subject to the most excruciating agony in one side of her face and neck. The pain came on whenever she swallowed anything: the act of deglutition proved invariably the exciting cause of the torment. She was at that time under the care of a practitioner, who had desired that she might eat mutton-chops three or four times a-day. Of course this was a sentence full of misery to her; but so desirous was she to get rid of her disease, that she resolved steadily to follow the enjoined directions. This plan was to be tried for at least a month; after that time, if she were no better, her mother had resolved to consult another practitioner who had been much recommended to her. I should say that she had already consulted a great number of medical men; for the malady had existed nearly two years. At the end of the month she was worse than at the beginning; and the new practitioner, Mr. Pennington, was called in. He acted, like a man of sense and sagacity, upon the fact that the act of swallowing always gave rise to the pain; and he advised that she should not attempt to swallow for twenty-four hours. That period passed without any return of the pain; but it immediately recurred upon her eating a morsel of bread. The result of this experiment, however, encouraged him to hope that the morbid habit might be broken through by a sufficiently long abstinence from swallowing. And as she had been subjected to a great variety of fruitless treatment, he gave her no medicine, but advised that she should refrain altogether from taking food or drink by the mouth. Nourishing injections, composed of beef tea with an egg beat up in it, or of milk, were thrown into the rectum, two or three times a-day. This plan was persisted in for a longer time than I should have supposed she could have endured it. No nutriment whatever was taken by the mouth for five weeks and three days, and no paroxysm of pain occurred. At the end of that

period the pulse sank suddenly, from between seventy and eighty, to thirty-five beats in a minute; and thereupon Mr. Pennington, thinking he had carried his experiment far enough, deemed it advisable to administer by the mouth a desert-spoonful of beef-tea twice a day. This was continued for four days without producing any return of the pain. A small piece of fish was then allowed, and afterwards some chicken; and proceeding thus cautiously, in the course of a month she was able to eat and drink anything, without the slightest inconvenience.

I should state, however, that some time afterwards, the neuralgia returned in another situation, affecting the left knee: and this was remedied by a different mode of treatment. She is since dead.

Dr. James Arnott bears strong testimony to the power of *violent body exercise*, as a prompt and very agreeable remedy in neuralgic (and rheumatic) affections. He is enabled to speak from experience of its value in his own person, as well as in other instances. Having at one period of his life been tortured for six months by a neuralgic pain in his face, he resorted, upon a subsequent return of the pain, to the remedy just mentioned; and he succeeded on *every* occasion of its accession, whether by night or by day, in putting a stop to the pain by exercise with heavy dumb-bells, and particularly by retaining them as long as he could with outstretched arms, in a horizontal position. Two or three minutes, he says, of such exercise will generally be enough; but the amount of it requisite will probably be proportionate to the degree of the morbid affection.

When other means fail, or in conjunction with other means, local applications to the affected part may be tried. Belladonna will sometimes materially palliate the pain; so will opium; but within the last few years a new anodyne has been brought into use; and it really seems to have been of essential service in several instances of this most painful disorder. I allude to *aconitine*: the active principle of the monkshood. The property belonging to this plant, of benumbing sensation, has long been known. Sir Benjamin Brodie found, many years ago, that after chewing its leaves, a remarkable numbness of the lips was left, which lasted some hours. We may understand therefore the beneficial operation of the aconitine upon a part of which the sensibility is unduly exalted. It is but recently that pure aconitine has been procured; and consequently it has not yet been very extensively employed, and the less so on account of its very high price; but what experience we have of it, as a benumber of pain, is highly encouraging. It has been of singular benefit to a surgeon who formerly lived in Charterhouse Square, and whose case is well known, I believe, to the profession. Mr. Spry had suffered greatly, for eight years, under very acute neuralgia, affecting the parts supplied by the lowermost or mental branch of the fifth pair of nerves. After exhausting almost every expedient that ever has been recommended for tic douloureux, except that of dividing the nerve, he was induced to make trial of the aconitine. It was mixed with cerate, in the proportion of one grain to one drachm, and a small portion of this was smeared over the track of the painful nerve once or twice a day for six days. By that time he had entirely lost the pain. He states, I understand, that the application of the ointment produced a sense of numbness, which continued for twelve, or eighteen hours. Dr. Hue, who first told me of Mr. Spry's case, told me at the same time that he knew of two others in which the same application had been equally successful. This encouraged me to try it upon my patient, whom I mentioned before, and who happened at that time to be in the hospital. I bought, for ten shillings, five grains of the aconitine at Mr. Morson's, in Southampton Row, where I knew it would be genuine. One-third of a drachm of ointment, containing one-third of a grain of the alkaloid, was smeared two or three times a day over my patient's face, and the attacks presently diminished in intensity, and in a few days ceased altogether. He soon after left the hospital, so that I cannot tell whether the cure was permanent. I presume it was so, as he did not return. The particulars of Mr. Spry's case have been published by Mr. Skey in the nineteenth volume of the *Medical Gazette*. It is now (1841) six years since the aconitine was applied, and the pain (as Mr. Skey has recently informed me) has never recurred. It used to be excited by gentle friction of the hand, or by a current of cold air, but Mr. Spry "can now face any wind or temperature with impunity."¹ In the same

¹ This gentleman is since dead.

paper Mr. Skey relates another instance of the utility of this substance in facial neuralgia. It occurred in one of his patients at St. Bartholomew's Hospital.

This is a remedy therefore which is not to be neglected. Even if it only allayed the pain for a time it would be highly valuable. But, judging from the instances now referred to, we may hope that, of some forms of tic douloureux, the aconitine may be found equal to the cure. It seems probable that the recurrence of the pain is sometimes kept up by the influence of habit; and will cease if the habit can for a while be broken. You must take care, however, to obtain a genuine article. The manufacture of aconitine is difficult, and therefore the cost is considerable. Mr. Skey, in the Bartholomew case, failed with some aconitine that had been imported into this country, but succeeded at once when he employed the same quantity of Mr. Morson's preparation. A strong and efficacious tincture of aconite is now in use. Dr. Hake has informed me that in a severe case of tic douloureux of the face, a saturated solution of iodine in this tincture achieved a cure, after the tincture alone had been applied in vain.

A few years ago Mr. John Scott published a little book on the disease we are now considering, with the professed object of introducing to general notice a species of local treatment which he had found successful in several long-standing and previously obstinate cases. It is well to be aware of these things, though probably the aconitine ointment will beat Mr. Scott's. Mr. Spry used Mr. Scott's ointment, but without benefit. It consists of the iodide of mercury, mixed with lard, in the proportion of two scruples to the ounce: and it is rubbed into, or placed in contact with, the affected surface, until some degree of irritation is produced.

Much may be hoped for, in this painful malady, from the cautious use of chloroform: present ease under its torturing paroxysms in any case; permanent ease when their recurrence depends, mainly or altogether, upon the force of habit. We must not expect that this anæsthetic agent will effect a cure if the pain result from some abiding cause of local irritation, or from some unredressed fault in the constitution at large. But in the worst instances it may abbreviate the periods of suffering, and give scope for the operation of measures more strictly sanative.

[In several cases of neuralgia, of different parts of the body, which, for a number of years, had resisted a variety of plans of treatment, we have known almost immediate relief, and in a few, a permanent removal of the disease, result from acupuncture. In other cases, however, no benefit has resulted from the operation. — C.]

There is a kind of *face-ache* which cannot properly be reckoned as a species of neuralgia, for it does not occur in short stabbing paroxysms, nor is the pain acute enough to entitle it to the name of tic douloureux; but which is very common, very distressing, and under ordinary treatment sometimes very intractable. It is called by some a rheumatic pain; it occupies the lower part of the face, the jaw principally, and the patient cannot tell you exactly whereabouts it is most intense. It is often thought to proceed from toothache, and bad or suspected teeth are extracted, but with no good effect. Now I allude to this for the sake of saying that some years ago I was instructed by an experienced old apothecary, that this *face-ache* might be almost always and speedily cured by the muriate of ammonia; — a medicine that we seldom give internally here, although it is so much used in Germany. And I have again and again availed myself of this hint, and been much thanked by my patients for the good I did them with this muriate of ammonia. It does not *always* succeed; but it *often* does. It should be given in half-drachm doses, dissolved in water, or in almost any vehicle, three or four times a-day. If the pain do not yield after four doses, you may cease to expect any benefit from it. In two or three instances of a similar kind that I have recently had to treat, I have found the iodide of potassium, in doses of five or six grains, work a speedy and permanent cure. This induces me to suppose that the pain in some of these cases is periosteal. I so judge from the ascertained efficacy of the iodide in other periosteal affections attended with pain.

Tic douloureux is the principal form of severe neuralgia which you may expect to meet with, in regard to acuteness of suffering and difficulty of cure. Two other forms, more common, and luckily more tractable, are generally spoken of under the

same head; *sciatica*, namely, and *hemicrania*. I have very little to say in this place, of either of these. *Sciatica*, or pain radiating from the sciatic notch, and following the course of the sciatic nerve, is sometimes an inflammatory complaint, and yields to the remedies of inflammation — cupping and blistering: sometimes it is plainly a part of rheumatism; and then may often be relieved by calomel and opium, or by colchicum: sometimes, again, it results from irritation within the pelvis, affecting the nerve before it emerges externally; this irritation may be connected with a disordered state of the kidney, and I suspect that it is in such cases that the oil of turpentine is of so much use: lastly, it is sometimes a purely nervous and neuralgic pain: and then the treatment applicable to facial neuralgia will, *mutatis mutandis*, be applicable to it. I had, some time ago, a butler under my care at the hospital, whom I am afraid I did not manage well. He suffered severe *sciatica*, and I had him cupped and blistered, and gave him a variety of medicines, for some time to little purpose: at last he got what I ought, I suppose, to have given him at first, viz., the carbonate of iron, and was presently well.

In a complaint so painful, so crippling, and oftentimes so obstinate, it is well to be provided with a succession of accredited remedies. One physician of my acquaintance cures all his cases of *sciatica* by putting a blister as large as half-a-crown over the spot where the nerve emerges, and sprinkling the surface exposed by the removal of the cuticle with half a grain or a grain of morphia in powder. Sulphur, again, has long been a popular remedy for rheumatism; and Dr. Fuller expresses his belief that in cases of rheumatic *sciatica*, unattended with fever, there is no external application so serviceable. The affected limb is swathed in flannel which has been thickly sprinkled with precipitated sulphur: over the flannel is placed a covering of oiled silk, or of thin gutta-percha; and the flannel bandages are kept thus applied night and day.

Hemicrania is simply headache, confined to one side, and occupying generally the brow and forehead, but sometimes affecting very exactly one moiety of the head. It is the *migraine* of the French, the *megrim* of our vernacular language; each of these terms being obviously traceable to the same Greek root. It is often attended with sickness; and in many instances it is periodical, coming on every day at a certain hour, lasting a certain time, and then subsiding. Like the other forms of neuralgia, *hemicrania* may be produced by various causes, which are, however, almost all of them such as tend to debilitate the system: it sometimes occurs in connexion with hysteria; sometimes it plagues women who have suckled their infants too long; sometimes it acknowledges the same cause as *ague*; and sometimes also it occurs independently of all other disease, and when no obvious exciting cause can be traced.

Whatever may be its origin, it is usually a very manageable complaint. When it is associated with evident anæmia, steel and the shower-bath may be expected to cure it. When its visits are strictly periodical, it will yield to quina. Arsenic is considered by many to have a specific power over the complaint; and I believe that four or six drops of the liquor arsenicalis, given three or four times a day, with due attention to the state of the bowels, will be almost sure to remove *hemicrania* in nine cases out of ten in which it occurs. But steel or bark, being milder and safer drugs, are *cæteris paribus*, to be preferred.

I say this disorder often acknowledges the same cause as *ague*; namely, the miasm of marshes, or malaria: and as that cause, mysterious as it is in some respects, exerts apparently its primary or chief influence upon the nervous system, and as *ague* has no definite seat in the human body, if it be not in the nervous system, I shall not find a more convenient place in these lectures for the consideration of *ague* than here, at the close of the remarks which I had to make respecting the diseases of the brain and nerves. In the next lecture, then, I shall begin to speak of Intermittent Fever.

LECTURE XL.

Intermittent Fever. Phenomena of an Ague Fit. Species and varieties of Intermittents. Predisposing causes. Exciting cause. Malaria: known only by its effects; places which it chiefly infests; conditions of its production; its effects upon the human body; influence of soils in evolving it.

I AM now to enter upon the consideration of that disorder of which the trivial English name is *ague*, and which is called by nosologists *intermittent fever*. This is one of the diseases which are known to us only in their respective group of symptoms. Before we can inquire successfully into its history, it is necessary that we have the group of symptoms which identify it set fairly before us. I must first, therefore, describe the *phenomena* of ague.

You will observe that ague resembles several other maladies that belong essentially to the nervous system, in being *paroxysmal*. A certain series of symptoms occurs, and then the patient reverts to a state of health: but this alternation commonly happens (or would happen if the disease were left to itself) a great many times. You may therefore look upon this succession of attacks as so many repetitions of a short distemper; or you may regard the whole period during which the attacks continue to recur at brief intervals, as being occupied with one single disease.

An ague fit is composed of three distinct stages; and they are severally named, from the phenomena that characterize them, the *cold*, the *hot*, and the *sweating* stage.

A person who is on the brink of a paroxysm of ague, experiences a sensation of debility and distress about his epigastrium; becomes weak, languid, listless, and unequal to bodily or mental exertion. He begins to sigh, to yawn, to stretch himself; and he soon feels chilly, particularly in the back along the course of the spine; the blood deserts the superficial capillaries; he grows pale, his features shrink, and his skin is rendered dry and rough, drawn up into little prominences, such as may at any time be produced by exposure to external cold, and presenting a surface somewhat like the skin of a plucked goose: hence it is called goose's skin, and in Latin *cutis anserina*. Presently the slight and fleeting sensation of cold, first felt creeping along the back, becomes more decided and more general: the patient *feels* very cold, and he *acts* and *looks* just as a man does who is exposed to intense cold, and subdued by it; he trembles and shivers all over; his teeth chatter, sometimes so violently that such as were loose have been shaken out; his knees knock together; his hair bristles slightly, from the constricted state of the integuments of the scalp; his cheeks, lips, ears, and nails turn blue; rings which before fitted closely to his fingers become loose; his respiration is quick and anxious; his pulse frequent sometimes, but feeble; and he complains of pains in his head, back, and loins; all the secretions are usually diminished; he may make water often, though generally he voids but little, and it is pale and aqueous; his bowels are confined, and his tongue is dry and white.

After this state of general distress has lasted for a certain time, it is succeeded by another of quite an opposite kind. The cold shivering begins to alternate with flushes of heat, which usually commence about the face and neck. By degrees the coldness ceases entirely; the skin recovers its natural colour and smoothness; the collapsed features and shrunken extremities resume their ordinary condition and bulk. But the reaction does not stop here; it goes beyond the healthy line. The face becomes red and turgid; the general surface hot and pungent and dry; the temples throb; a new kind of headache is induced; the pulse becomes full and strong, as well as rapid; the breathing is again deep, but oppressed; the urine is still scanty, but it is now high coloured; the patient is exceedingly uncomfortable and restless. At length another change comes over him: the skin, which, from being pale and rough, had become hot and level, but harsh, now recovers its natural softness; a moisture appears on the forehead and face; presently a copious and universal sweat breaks forth, with great relief to the feelings of the patient; the thirst ceases; the tongue

becomes moist; the urine plentiful but turbid; the pulse regains its natural force and frequency; the pains depart; and by and by the sweating also terminates, and the patient is again as well, or nearly as well, as ever.

This is surely a very remarkable sequence of phenomena: and it would appear still more remarkable if it were less familiar to us. The earlier symptoms are all indicative of debility, and of a depressed state of the nervous system. There is the same sensation of exhaustion, with incapacity of exertion, which is produced by fatigue. The sighing, yawning, and stretching, all notify debility. The paleness of the surface, and constriction of the skin, and collapse of the features, are all owing to the retirement of the blood from the superficial capillaries. The skin shrinks, but the parts containing the bulbs of the hairs cannot contract so much as the other parts, and therefore the surface becomes rough, and the hairs bristle up, or become erected in some degree. *Horripilatio* is the learned term for this state of the surface. The coldness of the skin is another consequence of the emptiness of its blood-vessels; and the tremors, which are always indicative of debility, seem to depend upon the coldness. The chattering of the jaws has been (it is said) so violent as to fracture the teeth. This you may believe or not as you please, but certainly the whole bed is often strongly shaken by the shiverings of the patient. The necessary accumulation of the blood in the larger and internal vessels offers a reasonable explanation of the distressed and anxious breathing.

In their attempts to render a "ratio symptomatum," authors have sometimes spoken of the hot stage as though it were a necessary consequence of the cold. But if the cold fit be in any sense or degree the cause of the hot fit, it can only be so partially. There must be some other cause; for these reasons. The cold stage may occur and never be followed by the hot; or the hot stage may come on without any previous cold stage; and when they do both happen, they are not by any means proportioned to each other. When we thus see that a supposed cause is not always followed by the effect, and that the effect is sometimes produced without the agency of the supposed cause, and also that the supposed cause and the effect are out of proportion to each other, we cannot but conclude that the supposed cause is at most but a partial and accessory cause. We can more easily conceive how the hot fit may conduce to bring on the sweating stage. The stronger action of the heart and the more forcible propulsion of the blood will fill the superficial vessels, and in this way the natural secretions may be restored. We see exactly the same thing happen when the force of the circulation is increased by exercise: the extreme vessels receive a larger supply of blood, and sweat ensues.

There are many curious facts to be observed in respect to the paroxysm of an intermittent, such as it has been now, in general terms, described. In the first place the paroxysm *returns*. Cullen makes this a part of his definition; and quibbling objections to his statement have been made, which are scarcely deserving of mention. Thus it is said that this circumstance should not have been introduced into the definition, because it is not *necessarily* or *universally* true; that the patient *may die* in the very *first* paroxysm; or that he may be cured by the proper remedies of ague, *before* a *second* paroxysm has time to show itself. But all this is captious trifling. The paroxysms, if the disease be left to itself, will recur for a certain length of time; and, unlike the paroxysms in many of the spasmodic diseases which we have lately been speaking of, they recur at regular periods, and often with singular punctuality. This is a circumstance which we should waste our time in attempting to account for. Dr. Cullen has tried to explain it on the principle of some diurnal *habit* of the body; but the truth is, that no *satisfactory* explanation of it has ever been given, and we must be content, for the present at least, to receive it as an ultimate fact; and doubtless a very strange and interesting fact.

For distinguishing some equally curious varieties of these successions and alternations of disorder and health, certain terms have, by common consent, been adopted by pathologists; which terms it is necessary that I should explain. The period that elapses between the *termination* of one paroxysm and the commencement of the next is called an *intermission*; while the period that intervenes between the *beginning* of one paroxysm and the beginning of the next, is called an *interval*. As the paroxysms are liable to vary in length, the intermissions may be very unequal, even when the intervals are the same. When the intermissions are perfect and complete, the

patient resuming the appearance and sensations of health, the disorder is an *intermittent* fever. When the intermissions are imperfect, the patient remaining ill and feverish and uncomfortable in a less degree than during the paroxysm, then the complaint is said to be a *remittent* fever.

But, confining ourselves for the present to intermittents, it is another curious property of this complaint that, although the intervals are commonly constant in each case, and quite regular, they differ in duration in different cases. Upon this circumstance is founded a division of agues into species. When the paroxysm occurs at the same hour *every day*, the patient is said to have *quotidian* ague. When it comes on at the same hour *every other day*, appearing and remaining absent day by day alternately, he is said to labour under *tertian* ague. The paroxysm, strictly speaking, repeats itself every *second* day: and if the species I first mentioned be fitly termed quotidian, that in which the fits occur on alternate days ought to be styled *secundan*. But nosologists have chosen to reckon the day on which the preceding fit happens as the first: and then the day on which the fit next to it will happen, in the species now under consideration, is the third. In the same way, when a paroxysm absents itself for two whole days, and then recurs, the complaint is called a *quartan* ague. These are the three principal species or types of intermittent fever. It follows, of course, from what I have been stating, that in the quotidian type the interval is twenty-four hours; in the tertian, forty-eight; and in the quartan, seventy-two.

Each of these types has some other characters peculiar to itself. Thus, the paroxysms of the quotidian ague begin in the morning; those of the tertian, at noon; those of the quartan, in the afternoon. These are the *rules*. You are not to expect to find them always or rigidly observed; for the most part you will find that they are observed. It is probable that quotidian paroxysms, occurring at noon or at night, have sometimes been ascribed to ague, when they were merely symptoms of some local disease or inflammation; or perhaps accessions of *hectic* fever. It is observed also of the paroxysms, that when the disease is about to yield, they often occur later day after day, before they take their final departure. This is called *postponing*, and when they occur earlier than their stated hour, the paroxysms are said to *anticipate*. Now a postponing quotidian may be deferred till noon. But when the disease is pursuing its regular undisturbed course, the rule is such as I have mentioned.

The three principal types differ from each other, not only in their respective intervals, and in the periods of the day at which the paroxysms severally commence, but also in the *duration* of the paroxysms; and in the proportions which the stages of these paroxysms bear to each other. The average duration of the paroxysm in the quotidian is ten or twelve hours; and of course the average duration of the intermission is nearly the same. The tertian paroxysm commonly begins at noon, and is finished the same evening; its average duration may be estimated at six or eight hours. And that of the quartan does not exceed four or six hours.

You must observe also that while the quartan has the longest interval and the shortest paroxysm, it has the longest cold stage; whereas the quotidian has the shortest interval and the shortest cold stage, but the longest paroxysm. To express these facts in mathematical language, the length of the paroxysm varies inversely as the length of the cold stage; inversely also as the length of the interval.

Of these three principal types or species, the tertian is by much the most common: but the quotidian and quartan are neither of them unfrequent wherever ague is rife.

I should tell you that there are other types also spoken of, as quintans and sextans: but they are scarcely worth our attention. It is probable that when they are noticed (and that is very rarely) they are merely irregular quartans, postponing perhaps for a day or two. They never prevail epidemically. Galen describes one of these; so does Van Swieten. Boerhaave talks of a septiman, and even octavans are mentioned; or if you desire still more of the marvellous, Pliny, the naturalist, informs us that a certain Improvisatore was in the habit of having a paroxysm once a year. It came exactly on his birth-day; yet he died at a good old age.

There are, however, some curious modifications of the three principal types; or rather of two of them, the tertian and the quartan. For instance, a paroxysm may occur daily, and yet the ague not be of the quotidian type, but of the tertian. The paroxysm of one day will differ from the paroxysm of the next, but exactly resemble that of the third day; while the paroxysm of the second day will be like that of the

fourth; and so on alternately. And these differences will be decidedly marked: the paroxysms of two consecutive days will come on at different hours, and will differ in duration and severity. This form of ague is called the *double tertian*. One case of this kind, very distinctly characterized, was some time ago under my care in the hospital.

There is another form of double tertian. Two fits shall occur on the same day — Monday, for example — one in the morning, the other in the evening; on Tuesday there shall be no fit; on Wednesday again two; on Thursday none; and so on. The Latin nomenclature is more precise than the English in denoting these variations. The form I have last mentioned, in which two dissimilar paroxysms occur every other day, is called tertiana *duplicata*, while the other form, in which there is a fit every day, but those on the alternate days resemble each other, is called tertiana *duplex*.

In the same way you may have a double quartan. In that case, a paroxysm occurs on two days in succession, and leaves the third day free; then it returns on the fourth day as it was on the first, and on the fifth as it was on the second, and leaves the sixth day free like the third, and so on. This is the quartana *duplex*. But two fits may happen on one day — say on Monday; none on Tuesday or Wednesday; and two again on Thursday. This is the quartana *duplicata*. Nay, the paroxysm of quartan ague may recur every day, and so far resemble a quotidian; but the fit of the first day will differ from those of the second and third, and resemble that of the fourth; the fit of the second day will be dissimilar from that of the first and that of the third, and like that of the fifth; and the fit of the third will be unlike that of either of the two preceding days, and find its counterpart in that of the sixth. This is a triple quartan: and where three paroxysms occur on the first day, which we will again suppose to be Monday, and none on Tuesday or Wednesday, but three again on Thursday, corresponding respectively to the first three, we have the quartana *triplicata*. And there are other complications still, with which I need not trouble you. In Dr. Cleghorn's book on the diseases of Minorca, you may find a very good and authentic account, evidently drawn from nature, of the irregular types and varieties of ague. They are well worthy of the attention of any among you who may be likely to practise abroad.

Some physicians have used the words *double tertian*, and so on, in the literal sense, and have supposed that two or more distinct agues coexisted. This savours of the error that I formerly warned you against, of looking upon diseases as separate entities, and not as merely modes of being and of acting, different from those which are proper to the state of health. The vulgar always regard disorders in this light. A coachman by whose side I sat while travelling from Broadstairs to Margate, was speaking of the rarity of ague in that part of the Isle of Thanet. His father, he said, once had the complaint, and a fit came on while he was on a visit to him, the coachman, at Ramsgate. The son administered to his suffering parent a glass of brandy: whereupon "he threw the agy off his stomach; and it looked for all the world like a lump of jelly." That was the only occasion on which he had ever "*seen the agy*."

Besides these varieties in *type*, some other deviations from the regular form of the paroxysm require to be noticed.

Sometimes the paroxysm is *incomplete*: it is shorn of one or more of its stages: the heat and sweating occur without any previous rigors; or the patient shakes, but has no subsequent heat; or the sweating stage is the only one of the three that manifests itself. These fragments of a fit are often noticeable when the complaint is about to take its departure; but they may also occur at other periods of the disease. Sometimes there is no distinct stage at all: but the patient experiences frequent and irregular chills, is languid and uneasy, and depressed. This state is commonly known among the inhabitants of our fenny and aguish districts as the *dumb ague*, or the *dead ague*; the patient is said not to *shake out*.

Again, there is often remarked a tendency to a change of type in the course of the same disease affecting the same person. Thus a quotidian may be transformed into a tertian; a tertian into a quartan; or, on the other hand, a quartan into either of these. I have already noticed the fact that the paroxysms may also alter their time of invasion, sometimes coming later and later in the day at each recurrence, sometimes earlier and earlier. When the paroxysm so *postpones*, the disease is getting milder: when

it *anticipates* its usual period of attack, the disease is increasing in severity. The postponement or anticipation, therefore, of the fit has a close relation to prognosis.

The most singular instance of variety that I have heard or read of, is referred to by Dr. Ranking (in his *Retrospective Address*, 1846), as recorded by M Maugenet. In this case the usual order of the stages was reversed. "The patient, upon each accession of the fit, was first attacked with profuse sweating, which lasted for an hour. Then the skin became dry and hot, and the face flushed, with headache, &c. This stage lasted ordinarily for five hours, when the patient began to feel cold, and eventually had distinct rigors." Quina was as effectual in this remarkable variety, as I shall presently show you that it is in the more regular form of ague.

There are yet other cases, in which from first to last no determinate type or order of succession is observed by the paroxysms; and these cases authors speak of as *erratic* forms of ague.

There are also many modifications or complications observable in the symptoms which constitute the fits. Occasionally each paroxysm is attended by violent delirium: this is most common, I believe, in the hot stage. This symptom has been known to be almost constant throughout an epidemic. Sometimes the patient is convulsed in the paroxysm; or syncope comes on; or tetanic rigidity; or petechiæ take place on the skin, and disappear with the paroxysm. These deviations from the common and regular kind and order of the symptoms may sometimes depend upon the constitutional predispositions of the person affected; but there is another way also in which they may be explained. I shall presently have a good deal to say upon the one grand—I may say *sole*—exciting cause of intermittents. Now exposure to that cause, a residence in aguish districts, will sometimes impart a periodic character to *other diseases*; and I apprehend that this explanation will apply to many of the instances which have been observed of hysterical, tetanic, or other paroxysmal complaints occurring at perfectly regular intervals.

The duration of ague—of the whole disease, and not merely of a separate paroxysm—it is not easy to estimate. If persons who laboured under it were always removed at once from the influence of the exciting cause, and were always suffered to remain without treatment calculated to check the malady, we might then find materials for determining its average natural duration. But we have not these data. In point of fact, ague sometimes consists of a very few paroxysms only, half a dozen, or four, or three, or even of one fit; and on the other hand they may be protracted over a space of several weeks, or months; nay, of many years.

An ague may attack a person at any time; but they are much more common in spring, and in autumn, than in the other seasons of the year; so that you will hear and read a good deal of *vernal* intermittents, and of *autumnal* intermittents. The autumnal agues are, *cæteris paribus*, the more severe and dangerous. The quotidian is most common in the spring; the quartan in the autumn; and the tertian is frequently met with both as a vernal and as an autumnal ague. You will bear in mind that in all this I am stating the prevailing *rules*; which are liable to numerous exceptions.

Ague is one of those disorders of which (as of common inflammation) all persons, at all periods of their existence, seem to be susceptible, when submitted to the influence of the specific exciting cause. Individuals of all ages, from sucking infants to persons of fourscore, are *liable* to it, but they are not *equally subject* to it. It is less likely (*cæteris paribus*) to affect the very young, and the aged, than those of middle life. However, the very old are by no means exempt from the operation of the cause of ague: and with respect to the very young, some extremely curious statements have been made. It is said that persons have had ague before they were born. We know that the period of intra-uterine life is obnoxious to many forms of disease; for we trace the consequences of such disease, in visible changes of structure, immediately after birth. Pulmonary tubercles constitute one malady to which the fœtus in utero is liable: hydrocephalus is another: acute inflammation of the peritoneum a third. And there can be no doubt that various specific poisons influence, occasionally, the included being, even although they may have no sensible effect upon the parent. The fœtus may thus contract small-pox, which sometimes proves fatal to it, sometimes not. The daughter of my bed-maker at Cambridge had a child ill of hooping-cough in the bouse with her while she was in the last months of pregnancy; and the infant in the

womb must have caught the disease, for I was assured that he hooped the very day he came into the world. The sins of the parent are thus visited often upon the child, when, before its first breath is drawn, its frame is contaminated by the virus of syphilis. And in like manner unborn infants are capable of being affected by the poison that produces ague. One case in proof of this recorded by Dr. Russell, in his *History of Aleppo*. The woman had tertian ague, which attacked her, of course, every other day: but on the alternate days, when she was well and free, she felt the child shake; so that they both had tertian ague, only their paroxysms happened on alternate days. Bark was prescribed for her; and it cured the little one first, and afterwards it cured the mother.

One probable reason why ague more commonly affects persons about the middle period of life, than those near its extremes, is, that the former are much more likely to be exposed to the primary exciting cause. And the same reason may be given, I presume, for another fact; viz., that the complaint is much more frequently seen in men than in women.

Among the circumstances which predispose to ague, debility has a powerful influence. It is important to be aware of this, as it concerns the prophylaxis, and the management of the patient after the disease has been subdued. Soldiers have been exposed to the exciting cause, without becoming affected by it, while strong and in good health; and have fallen ill of intermittent fever upon being weakened by exertion and fatigue. When I have told you that debility, any how produced, constitutes a predisposition to intermittent fever, I need scarcely add that all the multiform causes of debility may also be regarded as predisposing causes of this same disease; as they are of so many others.

But the strongest predisposing cause of all is an actual occurrence of the disease itself. The effect of former intermittents upon the system is such, that the complaint may be reproduced by agencies which under any other circumstances would be quite inoperative in exciting ague. I have stated already my persuasion that, strictly speaking, there is but one exciting cause of intermittent fever; but in making that statement I refer to its *first production*. The disease leaves the body in a condition in which other injurious influences may, of themselves, be sufficient to renew it. It brings into play a new order of exciting, or rather of re-exciting, causes. If a person were never exposed to the malaria, he would never, as I believe, have ague: but having once had ague, he may many times have it again, although he should never again be subjected to the direct influence of the malaria. The late Dr. James Gregory, of Edinburgh, had a brother-in-law who illustrated well in his own person the effects of predisposing circumstances in respect to ague. This gentleman was a strong active man, and commanded a battalion in the West Indies: and he escaped for a long time, while others were falling down around him in remittent fever. At last he was wounded by a musket-ball which passed through his shoulder. He insisted, much against the will of the surgeon of the regiment, on resuming his duties before his strength was completely restored; and the consequence was that he was immediately attacked by a remittent fever of such violence, that his life was for some time despaired of. But this was not all. The remittent disease assumed by degrees a distinctly intermittent form, and became a tertian: and at last he got well, and strong, and came over to this country. Yet for a long while, though to all appearance his health was re-established, ague-fits would from time to time occur; and they came precisely at the day and hour on which they would have happened if the tertian had continued with its original type; and slight causes were sufficient to reproduce them. He had marked, in an almanack, the days of the expected accession; and on those days it recurred, for some time, whenever the *east wind blew*. This very circumstance, the east wind, is a *common* re-exciting cause in such cases; exposure to cold in any way is another.

The curious fact which this instance exemplifies of the extension of the periodic law, in cases of relapse, throughout long intervals of apparent health, has since been noticed by Dr. Graves; who doubtless was not aware that Dr. Gregory had already observed the tendency thus lastingly impressed upon the system by the cause, or by the once occurrence, of an ague-fit. "The periodic rate is carried on, although (to quote Dr. Graves' happy illustration) as in a clock from which the striking weight

has been removed, the usual signal does not mark the termination of each certain definite portion of time."

The *exciting cause* of intermittent and remittent fevers—the primary exciting cause I mean, that without which ague would never occur at all—deserves a somewhat particular consideration. I need scarcely say that it consists in certain invisible effluvia or emanations from the surface of the earth, which were formerly called marsh miasmata, but to which it has, of late years, become fashionable to apply the foreign term *malaria*. In some respects the latter designation is the more convenient of the two.

The malaria is a specific poison, producing specific effects upon the human body. In its medical sense, it is not simply bad air, or impure air, although the word is loosely employed by many to express any mixed kind of contamination of the atmosphere. Thus we hear of the malaria of London: but ague, even when it occurs in London, is very seldom indeed, now-a-days, of London growth. The impure air incident to large and populous cities is prejudicial enough to health, as I formerly took occasion to show you, but it does not *generate* fever: neither continued fever, nor intermittent.

[If the author means to assert, as his language would seem to imply, that no form of fever whatever is generated by "the impure air incident to large and populous cities," but that all fevers are produced by its own "*specific poison*," resulting from other causes than those by which the atmosphere is rendered impure in the crowded, unventilated, and filthy lanes, courts, and alleys, which abound in suburbs of most large cities, he is certainly in error. That typhus, typhoid, and bilious fevers are generated in large and populous cities, no one, we presume, will pretend to deny; and evidence, as we think conclusive, has been adduced to show that the same is true of yellow fever; but of the dependence of either of those fevers upon a specific aerial poison we have not as yet been furnished with any satisfactory proof.—C.]

The emanations which cause ague have been called marsh miasmata, because they are notoriously common in marshy places. But they are not peculiar to marshy places. For this reason, and for brevity's sake, I prefer using the single word *malaria*. In this country, thank God, we witness its milder evils only, and those not very often; but it is the bane and scourge of large portions of the world. Whether you practise here or abroad, it is very fit that you should know the qualities, habitats, and habits, of this wide-spread poison. The mildest form of fever to which it gives birth is the intermittent fever, or ague; but in climates and places where it exists in greater abundance and intensity, the fever becomes remittent, or even assumes the continued form. This has led to strange errors, and proved a fertile source of difference and controversy amongst medical men: not a few of whom confound the severe continued fevers which spring from the malaria, and which are never contagious, with the severe continued fevers usually called typhous, which are unquestionably communicable from person to person.

The effluvia which thus form the sole exciting cause of intermittent and remittent fevers proceed from the surface of the earth, and are probably gaseous, or æriform: at any rate they are involved in the atmosphere. But they are imperceptible by any of our senses. Of their physical or chemical qualities we really know nothing. We are made aware of their existence only by their noxious effects; and the inference that they exist was not made till within the last century and a half. Time out of mind, indeed, it had been matter of common observation that the inhabitants of wet and marshy situations were especially subject to these definite and unequivocal forms of disease. But the Italian physician, Lancisi, was the first, so far as I know, to put forth distinct ideas concerning malaria, in his book, published about 1695, *De noxiis paludum effluviis*. This is the great original work upon the subject.

To the production of this deleterious agent, a certain degree of temperature seems necessary. It does not appear to exist within the Arctic circle: nor does it manifest itself during the colder seasons of more temperate climates. It is very seldom traceable beyond the 56th degree of north latitude; and it is supposed to require for its development a continuous temperature higher than 60° of Fahrenheit's thermometer. The nearer we approach the equator, the more abundant, virulent, and pernicious

does the poison become, wherever it is evolved at all. In this climate it gives rise to intermittents, and principally to tertians. As we go south, in Spain, and along the shores of the Mediterranean, the remittent becomes the predominant form; and (what is very instructive) remittents there contracted often improve into intermittents upon the removal of the patient to a colder climate. Under the tropical heats, in the West Indies, for example, the fevers very frequently assume the continued form.

And another condition of the development of the poison soon becomes apparent. It requires a certain degree of moisture. Of all these regions, malaria, showing itself always by its effects alone, infests certain parts only; which parts are, most generally, remarkable for their humid and swampy character. Thus, in this island, intermittents are produced chiefly, I may say almost exclusively, along the eastern coast; in parts of Kent, Essex, Cambridgeshire, Norfolk, Lincolnshire, and the East Riding of Yorkshire: and in each of these counties there are marshes, or fens, or low grounds and lands that are occasionally overflowed with water. Many of these spots have, within the last fifty years, been drained, and brought under cultivation; and agues are consequently much more rare in England than they formerly were. In Sydenham's time they were very frequent, and very fatal indeed, in this metropolis. James I., and Oliver Cromwell, both died of ague contracted in London. At present (as I said before) we seldom meet with them. Except in the year 1827, I have never, since I have been in practice, known ague to be at all prevalent here. This comparative freedom from malaria is mainly owing, no doubt, to the improved character of the draining and sewerage.

Agues, or aguish fevers, are endemic along every part of the low and level coast of Holland. In Italy, the Pontine marshes, near Rome, have possessed for ages an infamous celebrity of the same kind. The whole of the district called the Maremma,—stretching for about thirty leagues along the shores of the Mediterranean, and in some places ten or twelve leagues broad—is rendered dangerous, and almost uninhabitable, by the vast quantity of malaria annually evolved from its soil. In America large districts are, for the same reason, prolific of disease. The late Bishop Heber, in his *Narrative of a Journey through the Upper Provinces of India*, gives the following striking picture of the influence of the malaria in that part of the world. It seems to be alike pestiferous to man and beast.

“I asked Mr. Boulderson if it were true that the monkeys forsook these woods during the unwholesome months. He answered that not the monkeys only, but everything which has the breath of life, instinctively deserts them from the beginning of April to October. The tigers go up to the hills; the antelopes and wild hogs make incursions into the cultivated plain; and those persons, such as dâk-bearers, or military officers, who are obliged to traverse the forest in the intervening months, agree that not so much as a bird can be heard or seen in the frightful solitude. Yet during the time of the heaviest rains, while the water falls in torrents, and the cloudy sky tends to prevent evaporation from the ground, the forest may be passed with tolerable safety. *It is in the extreme heat, and immediately after the rains have ceased*, in May, the latter end of August, and the early part of September, *that it is most deadly*. In October the animals return. By the latter end of that month the wood-cutters, and the cow-men, again venture, though cautiously. From the middle of November to March troops pass and repass, and with common precaution no risk is usually apprehended.”

Persons who live in England might perhaps be disposed to think lightly of the malaria, had not such fearful evidence of its appalling power been brought home to the experience of our countrymen, in the early part of the present century, by the results of the unfortunate expedition to Walcheren. Sir Gilbert Blane has given an account of the ravages it there committed among our troops. You may see his paper, to which I shall presently again refer, in the third volume of the *Medico-Chirurgical Transactions*.

Not only a certain degree of heat, and a certain quantity of moisture, but the presence of all the four elements of the ancients, would appear to be requisite for the production of this poison. Air of course there must be; and earth also is essential. If heat and moisture were alone adequate, we should find the fever prevailing among sailors when out at sea; but it is not so, whatever may be the temperature under which they cruise. It is when they approach the coast, and land upon it, that they

are attacked. The water of marshes has been examined under the microscope, and analysed again and again, with a view to the discovery of the nature of this pestilential agent; but in vain. A more likely way to detect the noxious material would seem to be by examining the *air* of malarious districts; and this has been done carefully and repeatedly by expert chemists; and with the same want of success. The poisonous principle eludes the test of the most delicate chemical agents.

Where there is much heat, and much moisture, there we usually find also much and rank vegetation, and much vegetable dissolution and decay. The belief was as natural, therefore, as it has been general, that the putrefaction of vegetable matters was somehow or other requisite to the formation of the poison that exists so commonly in swampy situations. This belief has descended, almost unquestioned, from the time of Laneisi; and it obtains almost universal acceptance, I fancy, among physicians of the present day. Yet very strong facts have been adduced to show that the decomposition of vegetable substances is only an accidental, though a frequent, *accompaniment* of the miasm; and not by any means an essential condition of its evolution.

In the first place, the decomposition of vegetable matter goes on abundantly without the production of malaria. The rotting cabbage-leaves of Covent Garden, and those which taint the air of the streets from the neglected dust-holes of London, during the hot weather of summer, give rise to no ague. The same may be said of the putrefying and offensive sea-weed, which is deposited in large quantities upon some very healthy parts of our sea-coast. But the converse facts are the most remarkable and conclusive. I have stated that *marshes* are not necessary to produce malaria; but Dr. William Ferguson—a physician who had, and who well used, very sufficient opportunities of investigating the question—shows that *vegetation* is not necessary: that the peculiar poison may abound where there is no decaying vegetable matter, and no vegetable matter to decay. As the prevailing belief is, in my opinion, an erroneous one, and as it is really of great importance that correct views of this subject should be taken and disseminated by medical men, I will mention a few of the most striking of the facts detailed by Dr. Ferguson. They are contained in a very interesting paper “*On the Nature and History of the Marsh Poison*,” published in the *Edinburgh Philosophical Transactions*.

In August, 1794, after a very hot and dry summer, our army in Holland encamped at Rosendaal and Oosterhout. The soil, in both places, was a level plain of sand, with a perfectly dry surface, where no vegetation existed, or *could* exist, but stunted heath plants. It was universally percolated to within a few inches of the surface, with water which, so far from being putrid, was perfectly potable. Here fevers of the intermittent and remittent type appeared among the troops in great abundance. It is interesting to observe that the soil in Walcheren is precisely similar. Sir Gilbert Blane describes it as consisting “of a fine white sand, known in the eastern counties of England by the name of silt, and about a third part of clay.” It was after a dry and hot summer also that the British army suffered in that island from the endemic fever, to a degree which Dr. Ferguson speaks of as “being almost unprecedented in the annals of warfare.”

In the year 1809, several regiments of our army in Spain took up an encampment in a hilly ravine which had lately been a water-course. Pools of water still remained here and there among the rocks, so pure that the soldiers were anxious to bivouack near them for the sake of using the water. Several of the men were seized with violent remittent fever before they could move from the bivouack the next morning. “Till then (says Dr. Ferguson) it had always been believed amongst us that vegetable putrefaction (the humid decay of vegetables) was essential to the production of pestiferous miasmata; but in the instance of the half-dried ravine before us, from the stony bed of which (as soil never could lie for the torrents) the very existence even of vegetation was impossible, it proved as pestiferous as the bed of a fen.”

After the battle of Talavera, the army retreated along the course of the Guadiana river, into the plains of Estremadura. The country was so arid and dry for want of rain, that the Guadiana itself, and all the smaller streams, had in fact *ceased to be streams*, and were no more than lines of detached pools in the courses that had formerly been rivers. The troops there “suffered from remittent fevers of such destructive malignity, that the enemy, and all Europe, believed that the British host was extirpated.”

Cividid Rodrigo is situated on a rocky bank of the river Agueda, a remarkably clear stream : but the approach to it on the side of Portugal is through a bare open hollow country, that has been likened to the dried-up bed of an extensive lake ; and upon more than one occasion, when this low land, after having been flooded in the rainy season, had become as dry as a brick-ground, with the vegetation utterly burned up, there arose among our troops, fevers which, for malignity of type, could only be matched by those before mentioned on the Guadiana.

Many more facts to the same purpose are related in Dr. Ferguson's paper, which is in every way well worth your perusal. He tells us "that in the most unhealthy parts of Spain, we may in vain, towards the close of the summer, look for lakes, marshes, ditches, pools, or even vegetation. Spain, generally speaking, is then, though as prolific of endemic fever as Walcheren, beyond all doubt one of the driest countries of Europe ; and it is not till it has again been made one of the wettest, by the periodical rains, with its vegetation and aquatic weeds restored, that it can be called healthy, or even habitable with any degree of safety."

Our time will not allow of my extracting any further evidence on this point ; one circumstance of contrast, however, I am unwilling to omit.

The river Tagus is, at Lisbon, about two miles broad ; and it separates a healthy from a very unhealthy region. On the one side is a bare hilly country ; the foundation of the soil, and of the beds of the streams being rock, with free open water-courses among the hills. This is the healthy side. But the Alentejo land, on the other side, though as dry superficially, being perfectly flat and sandy, is most pestiferous. Moreover, in and near Lisbon there are numerous gardens, where they keep water, during the three months' absolute drought of the summer season, in stone reservoirs. These reservoirs, containing water in the most concentrated state of foulness and putridity, are placed close to the houses and sleeping rooms : the inhabitants literally live and breathe in their atmosphere. "Yet no one ever heard or dreamt of fever being generated amongst them from such a source ; though the most ignorant native is well aware that were he only to cross the river, and sleep on the sandy shores of the Alentejo, where a *particle* of water at that season had not been seen for *months*, and where water, being absorbed into the sand as soon as it fell, was *never* known to be *putrid*, he would run the greatest risk of being seized with remittent fever."

Now these facts, and facts like these, seem to prove that the malaria, and the product of vegetable decomposition, are two distinct things. They are often in company with each other, but they have no necessary connexion. Whoever, in a malarious country, waits for the evidence of putrefaction, will wait, says Dr. Ferguson, too long. For producing malaria it appears to be requisite that there should be a surface capable of absorbing moisture, and that this surface should be flooded and soaked with water, and then dried : and the higher the temperature, and the quicker the drying process, the more plentiful and the more virulent (more virulent probably because more plentiful) is the poison that is evolved.

The putrefaction of *animal* matter is sometimes spoken of as an element in the formation of the malarious poison. But the evidence I have just set before you refutes this supposition as completely as it excludes the alleged necessity of vegetable decay. I hope to prove to you, in a future part of the course, that neither animal nor vegetable decomposition is sufficient to generate fever of any kind.

Dr. Ferguson's facts are generally in accordance with the observations which others have made upon the same subject ; and his views will be found to account for some phenomena which the ordinary theory of vegetable putrefaction did not cleverly explain.

There is good reason for believing that in all cases the poisonous emanations proceed from parts of the surface that have been flooded and then dried, rather than from parts that are still wet or putrid. And this elucidates a circumstance very often noticed, viz., that neighboring places — especially high and low lands lying near each other — change their character in respect of salubrity upon the occurrence of rains. The low grounds, which had previously been very dangerous, become healthy when they are flooded over ; and the higher lands, which are made wet, and which rapidly dry again, produce the malaria abundantly. For the same reason, the edges or borders of swamps, which of course expand or contract according to the wetness or

dryness of the season, are more unsafe than their centres. The drying and half-dried margins of the purest streams may be prolific of the evil, when, from the want of confining banks, those margins have been flooded by the rising of the waters.

There is no observation more general than that, in malarious places, agues and remittent fevers abound more in hot and dry years than in those which are cold and moist. And this influence of temperature it is which mainly determines the differences observable in regard to these fevers at *different elevations*, and in *different seasons* of the year. In the higher grounds of the West Indies *agues* occur, as in this country: as you descend, and the mean atmospheric temperature increases, *remittents* are met with: and in the lowest and hottest parts the fever becomes *continued*. The following instructive facts are stated by Dr. Ferguson. In 1816, the British garrison of English Harbour, in Antigua, was disposed in three separate barracks, on fortified hills surrounding the dock-yard. One of the barracks was on an eminence named Monk's Hill, six hundred feet above the level of the marshes. The other two were situate on an eminence called the Ridge, one at the height of five hundred, and the other at the height of three hundred feet. So pestiferous were the marshes among which the dock-yard was placed, that it often happened to a well-seasoned soldier, coming down from Monk's Hill, and mounting the night-guard in perfect health, to be seized with furious delirium while standing sentry, and to expire within less than thirty hours after being carried up to his barracks, with a yellow skin, and having had black vomiting. Those in the barracks on Monk's Hill, *who did not come down*, the superior officers, the women, children, and drummers, had no fever of any kind. Seventeen artillerymen, in the barrack at the height of three hundred feet, did not come down to the night-guards. (We shall see hereafter that malarious places are always most dangerous at *night*.) Every one of these men was attacked with remittent fever, of which one of them died. At the barrack on the top of the Ridge, at the height of five hundred feet, there scarcely occurred any fever worthy of notice. Thus, *in the same place*, the malaria, in the level plain, caused continued fever, resembling, and I believe identical with, yellow fever: at the elevation of three hundred feet it gave rise to remittent fever: and at the height of five hundred or six hundred feet its influence was scarcely felt at all. In the neighbourhood of the Pontine marshes you see the villages perched curiously on the intervening hills; the Italians having been taught by experience that these elevated spots afford comparative security against the effects of the miasmata.

Wherever the malaria prevails, it produces its peculiar consequences chiefly in certain seasons: and it is in the autumn especially that agues and aguish fevers occur; that is to say, after the heats of summer: and the hotter and drier the preceding summer, the more frequent and fatal are the autumnal fevers. The Pontine marshes lie to the southward of Rome; and Horace, you know, says or sings,

*Frustra per autumnos nocentem
Corporibus metuemus austrum.*

The effects of these morbid effluvia upon the human body vary much under different circumstances. Where they are most concentrated and deadly, their operation may be almost immediate. Witness their speedy influence upon the soldiers who descended at night from Monk's Hill. So also sailors who have gone on shore for a single night only, have been attacked by the fever before they could return to the ship. On the other hand, when the emanations are less copious, or less virulent, there is sometimes a long and uncertain period of incubation. The disease remains latent, or the poison lies dormant, for a considerable space of time. Many of the soldiers who were exposed to the malaria at Walcheren did not experience its bad effects until after they had returned, and had even resided several months in England. In the same way, labourers, especially the itinerant Irish, will go down in the autumn for harvest work into Lincolnshire, and bring back the seeds of the disorder within them, and yet may not be attacked with ague for weeks or months; upon the occurrence of an east wind perhaps, or after unusual exposure to cold and wet. We trace, in all this, some analogy with the animal contagions; but the period of incubation is more irregular and accidental; and it probable that in many instances the ague would not happen at all, but for the concurrent operation of some other malign influence.

Another fact worthy of notice in respect to the agency of the malaria upon the

human frame, is that it affects strangers much more readily and decidedly than the natives of the place. In other words, habit mitigates the injurious effects of the poison. Persons become *seasoned* to it. At Walcheren, though almost every adult among the lower classes had laboured, in the course of his life, under the endemic intermittent, yet they were infinitely less subject to it than strangers: and they will not believe that their beloved birth-place is unhealthy. Sir Gilbert Blane says that persons of education, and even medical men, denied indignantly that their country was less healthy than any other; and attributed the sickness which raged among our troops to some trivial circumstance of diet or habits, and not to any insalubrity of the air. This is a curious moral feature; but a very general one. In the pestilential plains of Estremadura the superstitious natives, unable or unwilling to account for disease of a type so uncommon among the soldiers, from any unwholesomeness of the air, declared that they had all been poisoned by eating mushrooms.

It was found also, at Walcheren, that the strangers who survived the first attacks became thereafter much less liable to the endemic fevers. The French general, Monnet, who had held the command at Flushing for seven years, had acquired a knowledge of this fact, and endeavoured to turn it to practical account. He recommended that troops should not be frequently changed; for when it was the custom to send battalions from Bergen op Zoom every fourth night in succession, to work on the lines of Flushing, these men never failed, upon their return, to be taken ill in great numbers. General Monnet therefore advised, however displeasing it might be to the officers, that a stationary garrison should be retained at Walcheren, in order that the men might be habituated or seasoned to the air (*acclimatés*), and he added the instance of a French regiment which suffered in the second year of its being stationed there only one-half the sickness and mortality which it suffered during the first year; and hardly suffered at all in the third year.

But although the natives and residents in malarious places are not so liable as newcomers to the violent and distinct forms of fever, they are chronically affected by the insalubrity of the atmosphere. They are spoken of by travellers as being puny, sallow, and sickly; feeble in body and spiritless in mind; as having yellow faces, swelled bellies, and wasted limbs; as being subject to dropsies and fluxes; phlegmatic, melancholy, and short-lived.

One remarkable exception is mentioned by Dr. Ferguson. From some peculiarity or idiosyncrasy (which he conjectures may be somehow connected with the texture of the skin) the negro appears to be proof against endemic fevers. "To him marsh miasmata are in fact no poison; and hence his incalculable value as a soldier, for field service, in the West Indies. The warm, moist, low, and leeward situations where these pernicious exhalations are generated and concentrated, prove to him congenial. He delights in them, for there he enjoys life and health, as much as his feelings are abhorrent to the currents of wind that sweep the mountain tops, where alone the whites find security against endemic fevers."

No very certain or extensive observations have yet been made in respect to the *kind of soil* from which the miasmata are most apt to be extricated. Such as is loose, penetrable, porous, and sandy, appears highly favourable to their formation. So are soils which, containing much clay, are very retentive of moisture. One curious fact, however, bearing upon this question, seems to have been made out: viz., that what is termed peat-bog, or peat-moss, is not productive of malaria. Many parts of Scotland and of Ireland, that are occupied by large tracts of marsh, in which the peat-moss abounds, are completely free from these fevers. Dr. Bisset affirms that the exhalations from black peat-moss do not occasion intermittents, "at least in high moors under a clear sharp air." Now in the climate of Virginia, this counteracting influence of a sharp air can scarcely be looked for: yet it is a remarkable fact, that though the provinces of North America, especially North and South Carolina and Virginia, are full of ague, that disease is never seen among the inhabitants near the country of the *Dismal Swamp*, a moist tract of 150,000 acres on the frontiers of Virginia and North Carolina. Weld, the traveller, informs us, that this immense tract is covered with trees, and abounds with water, which appears the moment the shallowest trench is dug. The water is brown, like brandy, but quite clear, and not unpalatable. Its colour is ascribed by the inhabitants to the roots of juniper; and it is said to be diuretic. (CRAIGIE.)

LECTURE XLI.

Ague, continued. Speculations respecting its periodicity. Habits and properties of the malaria: most noxious at night: lies near the ground: is carried along by winds: cannot pass across water: attaches itself to trees: is diminished by the increase of cultivation and of population. Ultimate effects of the poison on the body. Ague formerly thought salutary. Prognosis. Propriety of stopping the disease.

YOU will remember the progress we made, at our last meeting, in the subject of intermittent fever. I described the ordinary phenomena of a paroxysm of ague; and afterwards mentioned certain unusual symptoms with which it is sometimes complicated. The three principal types of ague were also delineated; the quotidian, the tertian, and the quartan: as well as their respective characters, and intervals, and varieties, and changes of type. I spoke too of the predisposing causes of intermittent fever, which may all be briefly included under the head of circumstances that tend to debilitate the body: the strongest predisposing cause of all being a former attack of the disease. And I began to consider the great exciting cause of agues and aguish fevers; the malaria. I first directed your attention to the circumstances under which the malaria appears to be evolved. Since the time of Lancisi it had been very generally supposed that the humid putrefaction of vegetable substances was necessary to the production of this peculiar and wide-spread poison; and that heat accelerated the putrefactive process. That was Dr. Bancroft's opinion. That also is (I believe) the opinion held, and stated in lectures, by many pathologists at the present time. I showed you, from facts which rest upon Dr. Ferguson's authority, that this notion is founded in mistake: that the products of vegetable decay and decomposition may and do often coexist with malaria, but are distinct and separable from it, and by no means essential to its formation. There is reason to believe that the flooding of a porous earthy surface with water, and a subsequent drying of that surface under a certain degree of heat, constitute the sole or main conditions of the generation of the poison. We found that the effects of the malaria are modified by the temperature of the place: that in low and hot situations it may give rise to an affection not distinguishable in its symptoms from yellow fever; and that in proportion as the locality is higher and cooler, the fever tends to assume first the remittent, and then the intermittent type: that the period of incubation—the period which intervenes between exposure to the malaria and the invasion of the fever—is extremely variable in duration: that the poisonous effluvia affect strangers more certainly and more severely than natives of the place: that persons may become in some sort seasoned to the malarious districts: but that, with the exception of the negroes in the West Indies, the inhabitants of places much infested with the peculiar miasmata, are feeble, and sickly, and short-lived.

There was one point which I briefly adverted to, and dismissed perhaps too uncere- moniously: I mean the very curious fact of the *regular periodic recurrence* of the paroxysms of intermittent fever. I ought, I think, to have informed you of the views which pathologists have entertained respecting the explanation of that singular circumstance; although it must be confessed that the solution of the phenomenon is still to be sought for. A great number of persons have tried their hands, however, upon this question. Many of the earlier attempts at explanation are either quite hypothetical, or totally insufficient and illogical. Willis ascribed the intermission to a periodic development of the *fermentable matter* in the *blood*. But if any such development took place (of which we have no evidence) we should be no nearer the mark: the question would still recur, why the development of this matter should happen *periodically*: and the same remarks apply to various other so-called explanations brought forward by different writers of considerable reputation. Reil referred the intermit- tence of fevers to some *general law of the universe*; by which he meant, I believe, some vague generalization of such facts as the alternation of light and darkness, the periodic recurrence of the seasons, the ebbing and flowing of the tides, the succession

of appetite and satiety, of the states of sleeping and waking, and so on : but this evidently is no explanation at all. M. Bailly offers a very singular conjecture upon the subject : he attributes the periodic phenomena to the modification necessarily induced in the human system, and particularly in the function of circulation, by the alternate change of position from the upright to the recumbent, and from the recumbent to the upright, every twenty-four hours ; and he adduces in corroboration of this notion the alleged fact that animals, which undergo no such oscillation of posture, are not subject to intermittent fevers. But this is said not to be a fact. Rodet and Charpentier affirm that horses are liable to such complaints. Dr. Macculloch refers to the case of a dog which laboured under a regular tertian ague for some years : the cold paroxysms taking place always at three o'clock in the afternoon. Even if this were not so, M. Bailly's theory fails to account for the occurrence of *continued* fevers. If his views were correct, then we might avoid having ague by refraining from these changes of position from the vertical to the horizontal during sleep, and back again upon waking. More recently M. Roche has put forth the opinion that the attacks of ague are periodic, because the *causes* of them are periodic. And if this could be made out, the conjecture would carry with it some show of reason. He observes that the spring and the autumn are the seasons in which intermittent fevers chiefly break out, especially the autumn : and that during those periods there is a very sensible difference in the temperature and humidity of the atmosphere by day and by night, and even within the space of three or four hours ; that a consequent alternation of action and reaction is thus produced in the human body, and soon becomes an established habit. Throughout a part of the twenty-four hours, the operation of the miasmata is slight, or not manifest at all ; while during another part of that period it is in full energy, and at about the same time daily. The emanations (which he conceives to proceed from putrefying vegetable matter) are most abundantly disengaged during the hottest part of the day ; these watery effluvia are dissolved by the warm air to a certain amount ; but after sunset, they are again deposited, and deposited the more copiously in proportion to the coldness of the atmosphere at that time ; and coming in contact with the surface of the body, with the mucous membrane of the air passage, and perhaps also with that of the digestive organs, and being absorbed by those surfaces, they occasion the phenomena which constitute an ague fit. The influence of the miasmata being intermittent, we need not wonder, he says, that their effects should be intermittent too : and then he goes on to ascribe the repetition of the paroxysms, after the cause has ceased to be applied, to that tendency observable in the animal system to reproduce certain actions, simply because they have been produced before : in one word, to the effect of *habit*. At length the habit wears out ; which accounts for the spontaneous recovery of those who are removed from the malarious district.

It seems to be a very serious objection to M. Roche's theory, that the disease does not show itself, sometimes, for weeks or months after the patient has been exposed to the miasmata. His theory fails altogether also to account for the different *types* of intermittent fever. The differences of type are indeed *opposed* to the theory.

After all it is probable that Cullen had recognised a *part* though not the whole of the truth respecting the periodicity of intermittent fevers, when he ascribed it to some law of the animal economy whereby it is subjected, in many respects, to a diurnal revolution. "Whether it depends," he says, "upon the original conformation of the body, or upon certain powers constantly applied to it, and inducing a *habit*, I cannot positively determine ; but the returns of sleep and watching, of appetites and excretions, and the changes which regularly occur in the state of the pulse, show sufficiently that in the human body a diurnal revolution takes place." But he also is much perplexed with the differences of type ; and all that he can say on that point amounts to this — that as the three principal types observe, severally, a particular time of day for their accession, and as quartans and tertians are apt to become quotidian, these to pass into the state of remittents, and these last to become continued ; and that as even in the continued form daily exacerbations and remissions are generally to be observed — all this attests the agency of a diurnal revolution. Suggestions as to some of the influences whereby this diurnal habit or variation may possibly be created and perpetuated, have been thrown out by Professor Laycock, of Edinburgh. "In the first place (I am quoting from a lecture of his published in the 38th volume of the *Medical Gazette*), we find that the atmospheric tides attain their maximum and

minimum at certain hours of the day : for there are tides in the circumambient atmosphere, as well as in the circumambient ocean ; and therewith there are also changes in the electricity of the air, and the magnetism of the earth. From 8 to 10, A.M. and P.M., the barometer is at its maximum height ; the electric tension is at its maximum too ; and there is also the greatest maximum variation east of the magnetic needle at the same hours. From 4 to 5 o'clock, A.M. and P.M., the barometer is at its minimum, and so is also the electric tension. The respiratory movements, and of course the activity of the circulation, are likewise in connexion with these hours. About 4 or 5 o'clock in the morning, with a minimum temperature, a minimum electric tension, and a minimum height of the barometer, there is also a minimum consumption of oxygen. Further, I have ascertained by frequent inquiry, that sleep generally comes on about that hour after a feverish and restless night ; and what is more remarkable, the statistics of deaths in York show that the chances are in the proportion of 3 to 2, that the last sleep — the sleep of death — will occur at that hour."

A most interesting experiment, as it appears to me, performed by M. Brachet upon himself, shows in a strong light the influence of acquired habit in continuing certain unnatural states of the system when once they have been originated : the experiment connects itself also with the peculiar phenomena of intermittent fever. Towards the end of the month of October, in the year 1822, M. Brachet took a cold bath, at midnight, for seven nights in succession, in the river Saone. On the first occasion he remained a quarter of an hour in the river ; on the second half an hour ; till at length he was able to stay in the water a full hour at a time. After each bath he betook himself to a warm bed, and in a short time became affected with considerable heat, followed by copious perspiration, in the midst of which he fell asleep. At the end of the seven days M. Brachet ceased to repeat this experiment ; but what was his surprise at finding, on the following nights, between twelve and one o'clock, that all the phenomena of a true ague fit appeared in due order and succession ! As, however, this artificial paroxysm was not very severe, and as he felt quite well during the day, M. Brachet determined not to interfere with it ; but to observe the result. Six times it recurred with great regularity. On the seventh night after he omitted the baths, he was summoned, towards midnight, to a woman in labour : the ride to her house heated him, and on his arrival he kept up the heat by placing himself before a large fire, and from that time the febrile phenomena ceased to recur.

The facts and theories which I have thus brought roughly together, in respect to the periodicity of agues, are not without interest, but they show that we have yet much to learn on this subject. Granting that habit may have its share in continuing the regular recurrences, we want some explanation of the return of the second and third fit, after certain determinate intervals, to give a *beginning* to the habit. In respect to the quotidian, Dr. Cullen's *diurnal revolution* might come to the rescue ; but this principle evidently will not apply to the tertian type. I know of no two-day, or bidual habit. And the objection holds still more strongly in regard to quartans. Indeed, in quotidians themselves there is much difficulty in applying the explanation, for though by anticipating, or postponing, they *may* come on at different hours of the day, yet their usual and natural paroxysms occur, not in the evening, but in the morning, when, on the principle of diurnal habit, there should be the *least* tendency to exacerbation of febrile action.¹

In yesterday's lecture, I pointed out the favourite *habitats*, if I may so speak, of the malarious poison. I have still a few observations to make respecting its ascertained habits and properties. Some of the laws to which it is subject are of great practical importance, and ought to be popularly known ; much more ought every medical man to be familiar with them.

In the first place, all malarious districts are (as I have already hinted) much more dangerous *at night* than in the day time. Whether the poison be then more copiously evolved, or whether it be merely condensed and concentrated by the diminished temperature, or whether the body be at that time more susceptible of its influence, it certainly is most active and pernicious during the hours of darkness. To *sleep* at night in the open air in such places is almost to ensure an attack of the fever.

¹ I would beg to refer the reader to Dr. Holland's interesting chapter (in his *Medical Notes and Reflections*, published since these lectures were delivered) "On Morbid Actions of Intermittent *and* ind."

Lancisi was quite aware of this, and devotes a chapter to the question. "Cur juxta paludes noctu præsertim indormientes magis quam vigilantes lædantur." It has repeatedly been observed among the crews of ships, when off a malarious coast, that the sailors could go on shore in the day to cut wood, or for other purposes, with impunity, while the men who remained on shore through the night guarding the water casks, were many or all of them seized with the fever. Take one instance as a sample of many. It is recorded by Dr. Lind. In 1766 the Phoenix ship of war was returning from the coast of Guinea. The officers and ship's company were perfectly healthy till they touched at the island of St. Thomas. Here nearly all of them went on shore. Sixteen of the number remained for several *nights* on the island. Every one of these contracted the disorder, and thirteen of the sixteen died. The rest of the crew, consisting of 280 men, went in parties of twenty or thirty on shore in the day, and rambled about the island, hunting, shooting, and so on; but they returned to the ships at night; and not one of those who so returned suffered the slightest indisposition. Exactly similar events occurred the following year, with the same ship, at the same place, where "she lost eight men out of ten, who had imprudently remained *all the night on shore*;" while the rest of the ship's company, "who, after spending the greatest part of the day on shore, always returned to their vessel before night, continued in perfect health." Many more examples of the same kind are stated or referred to by Dr. Bancroft in his book on the *Yellow Fever*: a book which is rich in information respecting the malaria.

The reapers in the "Campo Morto"—a well-named part of the Maremma which I yesterday mentioned—are permitted to sleep for two hours about noon. They did so at that time without danger; but when the dews of evening have fallen down upon the earth, which serves them for their bed, it is then that the poison puts forth its most deadly power. Upon this principle Lancisi admonishes those who in summer travel through the Pontine marshes, not to do so *by night*, as many had been accustomed to do, in order to avoid the greater heat of the day: and similar advice is still given at Rome to all strangers. Though the passage requires but six or eight hours, there are numerous instances of travellers who, in consequence of their having crossed these fens during the night, have been attacked with violent and mortal fevers.

The practical lesson to be derived from a knowledge of this fact is too obvious to dwell upon. In malarious countries the open air at night must be avoided. "Early to bed" is always a good and wholesome rule; but the other half of the proverb "early to rise" becomes in such countries an unsafe precept. At least it is hazardous to *leave the house early*.

Secondly, the malaria *loves the ground*. It tends downwards. Whether this results from its specific gravity; or from its adhering to the moisture suspended in the lower strata of the atmosphere; or from some peculiar attraction for the earth's surface, I cannot tell you. There is reason to suppose that the poison combines somehow, or becomes entangled with fog: and fogs usually brood and settle, at night especially, upon the surface. This may be one reason why *lying down* to sleep in the open air at night is so very perilous; and why the *indormientes* suffer more than the *vigilantes*. The lower rooms of the same house may contain the noxious effluvia, while the upper are free. "In all malarious seasons and countries," says Dr. Ferguson, "the inhabitants of *ground floors* are uniformly affected in a greater proportion than those of the upper stories. According to official returns during the last sickly season at Barbadoes, the proportion of those taken ill with fever in the lower apartments of the barracks exceeded that of the upper by one-third, throughout the whole course of the epidemic. At the same time it was observed that the deep ditches of the forts, even though they contained no water—and still more the deep ravines of rivers and water-courses—abounded with the malarious poison." Dr. Hunter, in his work on the diseases of the army in Jamaica, says, "The barracks of Spanish Town consists of two floors, the first upon the ground, the second on the first. The difference in the health of the men on the two floors was so striking as to engage the attention of the Assembly of the island: and upon investigation it appeared that *three* were taken ill on the ground floor, for *one* on the other. The ground floor was not therefore used as a barrack afterwards." Mr. Ralph, in a table printed as an appendix to a paper of Dr. Ferguson's, in the eighth volume of the *Medico-Chirurgical*

Transactions, states the results of an inquiry into the comparative healthfulness of the upper and lower apartments of barracks in Barbadoes, to have been that the individuals residing in the lower apartments were attacked in the proportion of two to one of those living in the upper: and with certain apparent exceptions, which I shall notice presently, experience is uniformly in favour of the proposition that the poison is most prevalent and destructive near the surface of the earth, and does not rise high into the atmosphere.

To specify the sanitary precautions dictated by an acquaintance with this property of the malaria, must be quite superfluous.

Thirdly, the malaria is *moveable by the wind*. It is capable, therefore, of being carried *from* the spot where it was generated; and to other places which might else be free from it, and healthy. In this respect it is analogous to a heavy fog or vapour; and, in some cases, it is accompanied by a palpable mist; to which, perhaps, it may cling. The following passage relative to this subject occurs in Bishop Heber's *Journal*. "From Checta Talao our road lay through a deep and close forest, in the lower parts of which, even in the present season, the same thick milky vapour was hovering as that which I saw in the Terrai, and which is called *essence of owl*." This Terrai is the region which I mentioned in the last lecture as being so pestiferous, that it is deserted, during certain parts of the year, by every living creature.

This conveyance of the poison, like a cloud or fog, from one part of the surface of the ground to another, it is very important to attend to in all places; and especially so in tropical climates, where the wind blows for a long time together from the same quarter. We are thus enabled to account for the apparent exceptions to the last-mentioned property of the malaria, viz., its preference of low to elevated situations. You will readily understand how the miasmata may roll up, and hang accumulated upon, the side of a hill towards which a current of air sets steadily from or across a neighbouring marsh. Nay, the poison may be thus blown *over* a hill, and deposited on the other side of it. In this way, I presume, are to be explained the following curious facts, related in Dr. Ferguson's paper.

"The beautiful port of Prince Rupert's, in the island of Dominica, is a peninsula which comprehends two hills of a remarkable form, joined to the main land by a flat and very marshy square isthmus *to windward*, of about three-quarters of a mile in extent. The two hills jut right out on the same line into the sea, by which they are on three sides encompassed. The inner hill, of a slender pyramidal form, rises from a narrow base nearly perpendicular, above and across the marsh from sea to sea, so as completely to shut it out from the port. The outer hill is a round-backed bluff promontory, which breaks off abruptly in the manner of a precipice above the sea. Between the hills runs a very narrow clean valley, where all the establishments of the garrison were originally placed; the whole space within the peninsula being the driest, the cleanest, and the healthiest surface conceivable. It was speedily found that the barracks in the valley were very unhealthy; and to remedy this fault, advantage was taken of a recess or platform near the top of the inner hill, to construct a barrack which was completely concealed by the crest of the hill from the view of the marsh on the outside, and at least three hundred feet above it: but it proved to be pestiferous beyond belief. In fact no white man could possibly live there, and it was obliged to be abandoned. At the time this was going on, it was discovered that a quarter which had been built on the outer hill, on nearly the same line of elevation, and exactly five hundred yards further removed from the swamp, was perfectly healthy; not a single case of fever having occurred in it from the time it was built."

There is a striking anecdote given by Lancisi, showing, on a small scale, the effect of the wind in carrying the malaria with it. Thirty ladies and gentlemen had sailed to the mouth of the Tiber on an excursion of pleasure. Suddenly the breeze shifted to the south, and began to blow over a marshy tract of land situated to the windward of them. Twenty-nine of the thirty were immediately after attacked with tertian ague. So also Humboldt informs us that the town of Cariaco is afflicted with intermittents by the north-west wind conveying across it the miasmatic emanations of the Laguna of Campona.

And as the wind may thus transport the malaria to a distance, and thereby render a spot unhealthy which naturally might be salubrious, so also it is often of service in clearing the poison from other places, and preventing its concentration.

A knowledge of these facts ought to be valuable in determining the choice of encampments, and of sites for dwelling-houses in aguish districts. Settlers in hot climates, especially where trade-winds prevail, would do well to avoid founding towns on the lee side of any swampy or suspicious ground. The outlets of rivers are commonly selected, for the convenience of commerce: and there is often a right and a wrong bank. I believe that most of the principal towns in the West Indies are built, for the advantage of the outward bound vessels, upon the western, or lee side of the islands.

Fourthly, it is a singular, but well-ascertained fact, that the miasmata lose their noxious properties *by passing over even a small surface of water*. Probably they are absorbed by it. And this is another mark of their tendency downwards. Many instances have already been referred to, where some of the crew of a ship have landed on a malarious coast, and have all been attacked by the fever; while the rest of the sailors, who remained on board, continued all healthy and well, though the ship was close to the shore. You could not have a better or more striking example of this than what took place at Waleheren. "Not only the crews of the ships in the road of Flushing were entirely free from the endemic, but also the guard-ships which were stationed in the narrow channel between this island (Waleheren) and Beveland. The width of this channel is about six thousand feet, yet, though some of the ships lay much nearer to one shore than to the other, there was no instance of any of the men or officers being taken ill with the same disorder as that with which the troops on shore were affected." This Sir Gilbert Blane has told us; and it is curious that Sir John Pringle made the very same remark in the very same place in 1747. He is speaking of the diseases of the campaign in Dutch Brabant: especially in reference to four battalions which had remained for some time in Zealand: and he says, "But Commodore Mitchell's squadron, which lay all this time at anchor in the channel between South Beveland and the island of Waleheren, in both which places the distemper raged, was neither afflicted with the fever nor the flux, but amidst all that sickness enjoyed perfect health; a proof that the moist and putrid air of the marshes was dissipated, or corrected, before it could reach them."

It is probable that this peculiarity has led to an erroneous and contracted estimate of the space through which the poisonous effluvia may be wafted, upon land, by the wind. Although the distance to which they are capable of being so conveyed, without losing their morbid power, has never been precisely defined, there can be no doubt that it is considerable. In Italy, according to Dr. Macculloch, the poisonous exhalations of the lake Agnano have been ascertained to reach as far as the convent of Camaldoli, situate on a high hill three miles distant.

I say the miasmata may probably be absorbed by the water over which they pass, or hang; and this reminds me of an opinion entertained by some writers, that the fever may be caused by drinking such water. The following interesting facts, suggestive of this notion, are recorded by Mr. Grainger in his Report on the Cholera of 1848-49.

Dr. and Mrs. Evans, of Bedford, were both attacked with ague while staying at Versailles in the year 1845. The water used there for domestic purposes is brought from the Seine at Marli. A large tank in which it was collected for distribution to a particular quarter happened at that time to be damaged; and the mayor of the place provided a new supply of water, consisting of the surface drainage of the surrounding country, which is marshy. This water the inhabitants of Versailles would not drink; but Dr. and Mrs. Evans, living at an hotel, drank of it unwittingly. It was made use of by a regiment of cavalry also. The result was, that they who drank the water suffered intermittent fever of so severe a type that seven or eight of the soldiers died of it in one day. Upon careful investigation it was ascertained that those only of the troops were attacked who had drunk the marsh water; all the rest, as well as the townspeople, having escaped, though all of them breathed the same atmosphere.

He quotes another instance from M. Boudin. "In July, 1834, 300 soldiers, all in good health, embarked on the same day in three transports at Bona, and arrived together at Marseilles. They were all exposed to the same atmospheric influences, and, with one essential difference, supplied with the same food, and subjected to the same discipline. On board one of the vessels were 120 soldiers. Of these, 13 died of a destructive fever during the voyage, and 88 more were taken to the Military

Hospital of the lazaretto at Marseilles, presenting all the pathological characters proper to marshy situations. It appeared upon inquiry that the water furnished to the soldiers on board the affected ship had been taken, in the hurry of embarkation, from a marshy place near Bona, while the crew, not one of whom was attacked, were provided with wholesome water. It was further ascertained that the nine soldiers who escaped the disease had purchased water from the crew, and had not partaken of the marsh water. Not a single soldier or sailor suffered in the other transports, which were supplied with pure water."

Dr. Snow, who refers to these statements in his interesting volume on cholera, cites this additional evidence to the same purpose from the *Report of the Poor Law Commissioners on the Sanitary Condition of Great Britain*. "Mr. William Blower, surgeon, of Bedford, states that typhus and ague, which had long infested the village of Wooton, near Bedford, had been much diminished by digging a few wells, and obtaining good water. He states, also, that in the neighbouring parish of Houghton, almost the only family which escaped ague at one time, was that of a respectable farmer who used well water, while all the other families had ditch-water only."

This theory, even if its truth be conceded, of the occasional conveyance of the ague poison into the stomach by means of water as a drink, is by no means inconsistent with the belief that it most commonly operates through the medium of the atmosphere, and enters the body with the breath.

Fifthly, another remarkable property of the marsh poison, is its attraction towards, and its adherence to, the foliage of lofty umbrageous trees; so that it is very dangerous, in malarious places, to go under large thick trees, and still more dangerous to sleep under them. But this property, thus a source of peril to those who are ignorant of it, affords, when known and rightly made use of, a mode of protection and remedy against the influence of the miasmata. In the territory of Guiana, where large trees abound, the settlers live fearlessly, and unhurt, close to the most pestiferous marshes, and to leeward of them, provided that a screen or belt of trees be interposed. New Amsterdam, in Berbice, lies on the lee side of an immense swampy forest, in the direct track of a strong trade-wind that blows night and day, and pollutes even the sleeping apartments of the town with the stench of the marshes; yet it brings no fevers. The inhabitants are well aware that it would be almost certain death for a European to sleep, or even to remain after nightfall, within the verge of the forest. To cut down the trees would not only be a perilous operation in itself; but would let in pestilence upon the town.

This property also of the malaria, as well as the use to which it may be turned, was known to Lancisi. He describes the vast increase of agues and remittent fevers in Rome during the summer of 1695, after a great overflowing of the Tiber, by which the lower part of the city, and the fields adjacent, had been inundated in the preceding winter. The bad effects of this flood were felt throughout the whole of Rome, with the exception of one particular quarter, which was protected by a belt of trees around it. Lancisi even addressed a remonstrance to the Pope against a project which was entertained of felling some wood near the Pontine marshes, between them and the city. He endeavours to show that woods and groves were first made sacred, on account of their conservative influence in this way, to prevent their ever being cut down.

It would appear, from the facts I have just been detailing, that dwellings unfortunately built in the vicinity of marshes, might sometimes be rendered salubrious and safe by encircling them at a little distance by a hedge of trees—or (perhaps) even by drawing round them a broad moat of water. Such expedients, deserve, at least, a fair trial.

Sixthly, the generation and consequently the effects, of the malaria are prevented, or lessened, by culture of the soil. It is to this, that the diminution of agues in this country is mainly attributable. The fenny lands have been drained; and much of them brought under the plough. Dr. Craigie states that East Lothian, in Scotland, was at one time so productive of malaria, that for the reapers in harvest to be attacked with ague was quite a thing expected; but that now, in consequence of the perfect tillage, and the numerous tracts of wood with which the country is covered, the disorder is quite unknown there. Conversely, in regions which have been suffered to fall out of cultivation, intermittent and remittent fevers multiply. The more thoroughly

any country is cultivated, the more fully, in general, is it *peopled* also: and in many places the prevalence of these fevers has been observed to diminish and increase with the increase and diminution of the population. *Cæteris paribus*, agues are much less common in large towns than in country villages. This has been oddly enough accounted for by saying that populous cities are so full that there is no room for the malaria. A much more rational and probable explanation is that which attributes the freedom of crowded towns, and thickly inhabited districts, to the number of fires burned in them.

Many instances might be adduced to show that the more any place, naturally producing malaria, is depopulated, the more evident does the power of the poison become. The Italians date the introduction of the malaria into the Maremma, from the great plague in the sixteenth century, since which period the inhabitants of that district have never been sufficiently numerous to counteract the bad air, which increases as population and agriculture diminish.

Bishop Heber, in the narrative I quoted before, bears testimony to facts of the same kind with those I have now been stating. He says, "At the foot of the lowest hills, a long black level line extends, so black and level, that it might seem to have been drawn with ink and a ruler. This is the forest, from which we are still removed several coss, though the country already begins to partake of its insalubrity. It is remarkable that this insalubrity is said to have greatly increased in the last fifteen years. Before that time, Ruderpoor, where now the soldiers and servants of the Police Thanna die off so fast that they can scarcely keep up the establishment, was a large and wealthy place, inhabited all the year through, without danger or disease. The unfavourable change is imputed by the natives themselves to depopulation. The depopulation of these countries arose from the invasion of Meer Khân, in 1805. He then laid waste all these Pergunnahs, and the population, once so checked, has never recovered itself."

When persons having intermittent fever are unable to leave the unhealthy situation in which they have been exposed to the influence of the malaria—and especially when they are placed under unfavourable circumstances in respect to food, clothing, and shelter—the disease is apt to become exceedingly serious, leading to disorder of the sensorium, and great disturbance of the abdominal viscera, even in the intermissions; sickness, diarrhœa, dysentery, diseases of the liver.

[Dr. S. A. Cartwright, of Natchez, asserts, that the *jussieua grandiflora*, or floating plant of the bayous and lakes of lower Louisiana, has the power of preventing the development of malaria in regions particularly adapted to its generation. He affirms, also, that "it purifies all stagnant water in which it grows—that of the lakes and bayous inhabited by it, being as pure to the sight, taste, and smell, as if it had just fallen from the clouds." He ascribes to the presence of and the peculiar "hygienic or health-preserving properties of this plant," the remarkable exemption of the inhabitants of lower Louisiana from "malarious or miasmatic diseases." "The fact," he remarks, "that the region of country in which this aquatic plant abounds, is exceedingly healthy, can be established beyond cavil or dispute; it nevertheless contains more stagnant water and swamps than any other inhabited district, of the same extent, in the United States."—C.]

In Zealand, the biliary functions suffer so much during the complaint, that it is commonly known among the inhabitants of that country under the name of the *gall fever*. The frequent unnatural concentration of the blood in the internal parts may afford a reasonable explanation of these phenomena. When death takes place, morbid appearances present themselves such as might be expected; hepatic alterations; inflammation and ulceration of the mucous membranc of the alimentary canal: but the most characteristic morbid condition produced by repeated attacks of intermittent fever consists in enlargement of the *spleen*; with or without induration of its substance. That viscus is sometimes enormously increased in bulk, so as to be *felt*, and even its outline *seen* through the integuments of the abdomen. It has been known to weigh nearly eleven pounds. So common is this state of the spleen that it is familiar to the observation of the vulgar, who have even given it a name; it is called among

the inhabitants of the fenny parts of this country, the *ague cake*. I believe that whenever the abdominal circulation is much embarrassed, and the abdominal veins gorged, as they must be during the cold stage of an intermittent, the spleen in particular becomes distended with blood. Constantly we see this happen when the passage of the blood through the portal vessels is impeded by disease of the liver. Now this distension may not thoroughly subside perhaps at once. If the paroxysms of ague be frequently repeated, we may understand how the spleen may become fuller of blood on each successive occasion. It may be that a portion of the blood coagulates; or that inflammation of a slow kind is set up in the stretched covering of that organ. At all events, this is a very common sequel of ague: and it can scarcely be doubted that the repeated congestions of the internal vessels and viscera are the determining causes of the ague cake.

Independently of the paroxysm of ague, there is ample evidence to show the injurious influence of the malarious districts upon the general health. In this country such effects are not much seen; but in places where the malaria is more constantly and abundantly present, the race of inhabitants deteriorates. There stature is small; their complexion sallow and yellowish; they are prematurely old and wrinkled; even the children early acquire an aged aspect; and the spirits and intellects of those who dwell in these unhealthy spots are low and feeble, and partake of the degeneration of their bodily qualities.

It is therefore strange that a notion should ever have prevailed, of the *salutiferous* effects of an attack of ague. But such a notion may be traced from very nearly our own times up to the earliest records of physic. The late Dr. James Sims, who was a physician of some note in this town, felt convinced, at the commencement of the illness which terminated his life, that he should recover if he could catch an ague: and he went down into one of the marshy districts expressly for that purpose; but returned to London without having succeeded, complaining that the country had been spoiled by draining, and that there were no agues to catch. The superstitious Louis XI. entertained a similar opinion, and prayed to the Lady of Selles that she would confer upon him a quartan ague. Our monarch, James the First, had more sensible notions on that score. There is an old English proverb which says, "An ague in the spring, is physic for a king;" and when this was repeated to him by his courtiers, he, being then ill of that disease, answered that the adage might be applicable to a young man, but that it would not do for an old one like him. In fact, as I mentioned before, he died of his ague. The same doctrine has, however, been handed down to us by the father of physic himself. Hippocrates says, in the fifty-seventh Aphorism of his fourth Section, *υπο σπασμον, η τετανον ενοχλουμενω, πυρετος επινοημενος λυει το νοσημα*. And Celsus, in his capital digest of the medical knowledge of his time, preserves the same opinion, with some apparent astonishment that it should be true. "Denique ipsa febris, quod maxime mirum videri potest, sæpe præsidio est." I recollect hearing Dr. Graham, the professor of botany in Edinburgh, relate the following anecdote in one of his clinical lectures:—His brother was intimate with the professor of natural history at Cremona; and this gentleman was resolved to put the truth of the aphorism that I have quoted from Hippocrates to the test. Accordingly he sent a patient afflicted with *epilepsy*, to pass a night or two in a marshy place, where the malaria was known to be so abundant, and so powerful that few escaped ague, who were there exposed to its influence; and the two-fold design succeeded admirably. The patient got an ague, and lost his epilepsy. The worthy professor contented himself with moderating and keeping in check the new complaint, thus intentionally produced, for a period of six months, when he administered its *coup de grace* in a few doses of Peruvian bark; and the epilepsy never returned. If I had believed that this could have been anything more than a mere coincidence, I should have told you of it before, when I was speaking of the treatment of epilepsy. I should rather imagine the notion thus prevalent for so long a time, that ague had a salutary tendency, and that it was wrong to stop it too soon, to have originated in the difficulty which physicians found in stopping it, before its cause was so well understood, and the specific for it was discovered. They found it obstinate under the feeble and inert methods then employed, and therefore they endeavoured to persuade their patients, and perhaps themselves also, that the disease had better proceed a certain length.

I have very little to say, in addition to what you must have inferred from what I have already said, as to the *prognosis* in intermittent fevers. In cold countries, such as ours, it is almost always favourable. Of course it will be modified by the previous condition of the patient: if he were beforehand the subject of serious organic visceral disease; or if he be very old or infirm; the supervention of ague may destroy him. But to persons of tolerable health and strength prior to the setting in of the ague, we may confidently promise a *cure*. In warm countries intermittent fevers are much more dangerous: and are sometimes very rapidly fatal. They are often accompanied by most severe affections of the head, stupor, delirium, convulsions; and of the alimentary canal, diarrhoea, sickness, and not unfrequently the black vomit. They are prone also, in those climates, to run into the remittent or continued form; and this tendency is shown by long protracted paroxysms, or by the anticipation or doubling of the paroxysms. In all countries quartans are cured with more difficulty than either tertians or quotidians. And quartans are most common in the autumn: and accordingly autumnal intermittents are more pernicious and intractable than the vernal. This fact has passed into a proverb in Italy; which proverb has been thus translated into Latin, "*Febris autumnalis — vel est longa, vel lethalis.*" The longer intermittents have lasted, the more difficult also are they to cure; and certainly there is much more danger of *visceral disease* in those that are of long standing.

It is probable that agues, such as we see in this country, would generally, under favourable circumstances, terminate in spontaneous recovery, provided that the patient could be put beyond the further operation of the malaria, protected from exposure to wet and cold, and suitably nourished. But possessing as we do a specific cure for ague, there would be no sense in our allowing the experiment of a spontaneous recovery to be made: or rather we should be inexorable, knowing as we do that the complaint is the more obstinate the longer it has lasted, and that it tends to the establishment of organic visceral disease, we should be without excuse if we did not stop it as quickly as we can. The disease is always distressing to the patient, and always debilitating. It may be dangerous, even in these climates, to weak or old persons: and it is dangerous to all persons in hot climates. "If the first fit (says the wise and observant Heberden) has been marked so clearly as to leave no doubt of its being a genuine intermittent, the remedy should be immediately given in such a manner as to prevent, if possible, a second." There needs very little preparation of the patient before administering the specific substance which is to cure him; and which every one here knows, before he hears me say so, to be the celebrated Peruvian bark, or its active principle as presented by the salts of quina. The old practice was to wait a few returns of the fits, either till some hypothetical ferment had taken place, or until supposed morbid matter had been expelled by vomiting or purging. There is, however, one very simple and short preparative which I am in the habit of using, and which I learned at Cambridge. You are aware that Cambridge is situated on the very edge of the fenny country which extends along that part of the east coast of the island. Numerous patients afflicted with ague come in from the surrounding villages; and Dr. Haviland found that many of these had taken quina before they applied for assistance as out-patients at the hospital: but with very poor success. Now these cases readily gave way—the patient remaining in all other circumstances as before—after the operation of a calomel purge. I have adopted this practice, therefore, upon his recommendation; but it does not delay the specific treatment. I generally prescribe three grains of calomel with six or eight grains of rhubarb at bed-time, and commence with the quina the next morning. Very lately, in perusing the late Dr. Baillie's posthumous volume, I met with the following passage:—"I have known a good many cases in which bark alone would not cure an ague. In all these cases, as far as I now recollect, when a grain of calomel was given every night for eight or ten nights, bark cured the ague in the course of a few days. This practice I learnt from my friend Dr. David Piteairn."

I believe that calomel given once in a purgative dose is enough.

But first of all, what is to be done for the patient while he is in the fit? I confess to you that I seldom give myself much concern on that head. In ague, as we see it in this country, nature generally prompts the patient what to do: to cover himself up in bed, and apply warmth to his feet, and to take some hot drink, during the rigors; to adopt a cooler regimen during the hot stage; to wipe his skin dry, if the

sweating should be very profuse or protracted. But in hot countries, and in severer forms of intermittent, the patient really requires some help; and therefore I must consider shortly in the next lecture the management of the paroxysm; and I am the more bound to do so, because certain measures which I do not think necessary or judicious, at any rate for the complaint as we see it here, have lately been strongly recommended during the ague fit.

LECTURE XLII.

Treatment of Intermittent Fever; during the paroxysm; during the intermissions. Prophylaxis.

I WAS about, when we last separated, to consider the treatment of ague: first, during the paroxysm; secondly, during the intermissions.

In this climate we need not, I say, enumber a patient in an ague-fit with too much help. But in hot countries, where the disorder is apt to run into the remittent, or even the continued form, and where, during its violent and rapid course, internal organs are liable to sustain serious damage, the best, and indeed almost the only time for the effectual interference of the physician is in the first assault or paroxysm of the disease.

The objects of treatment during the paroxysm are, to alleviate the uneasy sensations of the patient; to abridge, if possible, their duration by shortening the fit; and to avert the danger which, under certain circumstances, may arise from intense internal congestion long continued, or from the severity of particular symptoms.

Now in the cold stage of ague, *diluent drinks* have been recommended, and *cordials*, and *external warmth*, and *opium*, and *emetics*, and *blood-letting*. One would suppose that if some of these expedients were useful, others could scarcely be so too. The *diluent drinks* are very proper: and I should allow the patient to use his own discretion in the choice of them. It was customary, formerly, to prescribe medicated drinks of this kind; and one pleasant, but neglected pisan still lingers in our Pharmacopœia, the *decoctum hordei compositum*. Now-a-days we are contented with the simple barley-water, toast and water, weak tea, gruel, and the like. These diluents should be taken warm, and for persons who are very feeble or exhausted, they may be made gently *cordial*: weak negus, for example, or white wine whey, may be given.

External warmth, being what nature and common sense would suggest, is certainly advisable and beneficial in the cold fit; even the warm bath, if it can be procured. In some places it is the custom to await an expected fit in the warmth bath. When this cannot so conveniently be obtained, the pediluvium may be employed; or the patient may be put into a warm bed, and have bags of hot salt or brain applied to his epigastrium; and a hot bottle, or a hot brick, wrapped up in flannel, to his feet. Or, what perhaps, is best of all, he may have a hot-air bath *applied to him*, as he lies in bed. This may be very easily done by means of a semicylinder or cradle of wicker work, closed at one extremity by a board. This is laid over the patient, and then covered with blankets. Through a hole in the centre of the board, one end of a curved iron tube is passed; the other end, expanded into a bell, looks downwards; and a spirit lamp being placed beneath it, the air between the wicker work and the sick person is soon made very hot. This apparatus was constructed many years ago, by Dr. Gower, when he was physician to the Middlesex Hospital; where its utility has been fully proved. External warmth applied in some one of these ways, affords singular comfort oftentimes, and contributes to shorten the cold stage. And the same may be said of friction, with stimulating liniments, along the course of the spine. Lind found that, in children, rubbing the spine with an embrocation composed of equal parts of soap liniment, and laudanum, at the approach of the cold stage, often prevented the paroxysm.

Opium has often been exhibited in the cold stage, with the view of cutting short the fit; and not without some success. The strongest evidence of its usefulness in that stage of the paroxysm is furnished by Dr. Trotter, in his *Medicina Nautica*. Agues being very frequent among the crew of the *Vengeance*, he resolved to try the full effect of opium in preventing the fit. At its first approach a dose of laudanum (never less than thirty drops) was given: if this did not bring on some warmth within ten or fifteen minutes, from twelve to twenty drops more were administered. In most cases, "in a few minutes an exhilaration of spirits was perceived: the pulse from being weak, quick, and sometimes irregular, became full, less frequent, and equal; an agreeable warmth was diffused over the whole frame, and every unpleasant feeling vanished, sometimes in a quarter of an hour. The patients were themselves surprised at the sudden change in their sensations." Dr. Trotter speaks of these as being the completest cures that ever came under his observation. If, at the next period, the paroxysm threatened to recur, the opiate was repeated always with the same success. "Few instances were met with where any indisposition indicated a third attack, at the expected period of accession." Notwithstanding this testimony, it appears that opium is still better adapted to another stage of the paroxysm.

Emetics were formerly much prescribed in the cold stage, at its earliest approach. Cullen recommends them; and they may sometimes be useful, in spite of Chomel's assertion that they are always hurtful. That they have gone so much out of fashion is, however, a proof that they cannot be depended upon for cutting short the paroxysm. Vomiting is itself no small distress to many persons; and for my own part, I should not think of giving an emetic unless some indications of a loaded and oppressed state of the stomach were present; such as nausea, an ill taste in the mouth, a coated tongue, and foul breath. A scruple of ipecacuanha will, even then, be sufficient. The object is to empty the stomach effectually but mildly. I would not give antimony. Irritability of the stomach, in the more violent of these fevers, is too apt to arise spontaneously. Sir Gilbert Blane tells us that the greatest impediment to the cure of the severer intermittents at Walcheren, in their early stages, proceeded from the extreme irritability of stomach, which made it difficult to administer the requisite medicines. In hotter climates nausea and vomiting are still more common and more urgent; and we have to guard against the risk of inducing or aggravating these symptoms. "Emetics (says Dr. Mackintosh, in his *Practice of Physic*) have been often extolled, but I believe every experienced tropical physician will agree with me in cautioning young practitioners against their indiscriminate employment. Irritability of the stomach is one of the most frequent and troublesome symptoms; and once excited, it is always difficult, and in many cases impossible, to restrain it. I have seen emetics exhibited, and the vomiting has continued till death, in spite of every remedy."

[We have repeatedly prevented the accession of the chill by administering to the patient, just before the period when it was expected, an emetic of ipecacuanha, and after this had ceased operating, immersing his feet in hot water, and, as soon as he is placed in bed, giving him from 30 to 40 drops of laudanum, or a teaspoonful of the camphorated tincture of opium. By this treatment not only is the chill prevented or shortened, but the whole paroxysm is often rendered milder.—C.]

Lately, the practice of *blood-letting* in the cold stage has been revived (for it is not a new practice), and strongly recommended, by the physician whose name I have just mentioned; and whose opinion carries with it the more weight from its having been founded on much personal experience in the treatment of these fevers. Dr. Mackintosh affirms that bleeding, performed in the cold stage, will often stop at once the paroxysm, and with it the disease: that even when its curative effects are less decisive, it will generally stop the cold stage, and shorten the paroxysm, and mitigate its severity, and afford speedy and great ease to the distressful sensations of the patient; and that any subsequent paroxysms which may occur will be mild and few. One bleeding, he says, is commonly sufficient: sometimes two are required; seldom more than two. The blood is to be suffered to flow till the patient feels relief: which usually consists in liberation from pain of the head and loins; freedom of respiration; the departure of the painful sensation of cold; and the cessation of the tremors and

of the debility. Most of the patients fall asleep after the operation. These effects have been produced by the abstraction of an ounce and a half of blood; they have sometimes (but rarely) required for their production twenty ounces.

Now this is the piece of practice to which I adverted at the close of yesterday's lecture, as being, in my humble opinion, inexpedient, and not to be recommended; at least in the agues of this country. I have seen a good many cases, first and last, and certainly I have never seen one in which I could have thought such a heroic remedy necessary, in the cold stage; if indeed it be, in that stage, a remedy at all. But I do not desire to oppose my experience alone, or my judgment, to that of Dr. Mackintosh. His method has been tried, since he first made it public, by various practitioners in this country. Drs. Townsend and Law, of Dublin, found it fail in the majority of cases. In Dr. Stokes's hands, the most usual effect of blood-letting in the cold stage was, to check the shivering; and, next to this, to mitigate its severity, without abridging its duration. In most instances, no modification was produced of the hot and of the sweating stages. In Dr. Kelly's experience, the general effect was, to shorten the cold stage, and to render the hot one milder; but in some cases it seemed to aggravate the symptoms. Mr. Gill found that, although the blood-letting might cut short the cold stage, it appeared to lengthen the period of febrile disturbance.

Confining myself, then, to intermittents as they show themselves in this climate, I cannot advise you to adopt the practice introduced by Dr. Mackintosh — of bleeding in the cold stage. I object to it because it appears to me quite unnecessary; because it is not such as the nature of the symptoms would suggest; because it tends to produce subsequent debility, which we should not needlessly inflict; and because the experience of other sober-minded men, who have given the method a fair trial, does not bear out the statements made by Dr. Mackintosh in respect to its usefulness.

At the same time, after a careful perusal of nearly a hundred cases adduced by Dr. Mackintosh to illustrate the efficacy of this measure, I think it highly probable that blood-letting may constitute the most important part of the treatment, in the very outset of the severer malarious fevers of hot climates; attended as they are with a degree of internal congestion and disturbance which is dangerous to the integrity of vital organs.

[Mr. Twining, in his work on the Diseases of Bengal, bears strong testimony in favour of bleeding in the cold stage of intermittents. In the greater number of cases he has found it to arrest the paroxysm; that is, the occurrence of the hot and sweating stages is prevented. In the majority of patients, when the bleeding has been preceded by a course of mild purgatives, there will be no return of the disease, provided attention is paid to keep the body properly clad and to guard against exposure to atmospherical vicissitudes. In this manner, he remarks, we cut short the fever, and guard against those ulterior visceral engorgements and indurations, by which it is too often prolonged, until the constitution is completely ruined.]

The only period of the cold stage at which bleeding is proper, Mr. Twining states to be, at the very commencement of the rigor, or just when the coldness and shivering are completely established. He has found that, in general, it is sufficient to take from an adult twelve or fifteen ounces of blood, and in the most robust European he would limit the quantity to be taken at one bleeding to twenty ounces. After the arm is tied up the patient should be permitted to lie quiet in bed for an hour or two — but not heated by being covered with too many bed-clothes; he should be immediately supplied with a cup of warm tea, gruel or thin soup.

According to Mr. Twining, "the requisites to ensure success from bleeding in the rigor, are, 1st, the preliminary course of moderate purging; 2d, that the blood be taken, from a large orifice, quite as soon as the coldness and rigor are fairly established; and 3d, that the patient be bled in a recumbent posture, and no more blood be taken than is sufficient to arrest the paroxysm."

In robust plethoric patients, who, during the intervals of the paroxysm, complain of headache, and morbid tenderness on pressure over the abdomen, and pain or uneasiness in the chest, the disease will seldom be arrested by the first bleeding; in many cases, they will have repeated paroxysms, in each of which the use of the lancet will be required. Patients, also, in whom the paroxysm, more especially the cold stage,

is attended with vomiting, Mr. Twining has found to require the repeated abstractions of small quantities of blood during the rigors. — C.]

If in this country, bleeding be requisite at all, it is in the *hot* stage. But it is not requisite at all, except when there appears to be danger of some internal inflammation. The best remedy of the *hot* stage is undoubtedly opium. Dr. Lind, who wrote after large experience, says that he never saw a person die in the cold fit, but had known several carried off in the hot one, with strong convulsions and delirium. He happened to notice the beneficial effect of an opiate given while the patient was very hot and feverish. He determined therefore to make further trial of opium in the paroxysm. "Having at that time (says he) twenty-five patients labouring under intermittent fevers, I prescribed an opiate for each of them, to be taken *immediately after* the hot fit, provided the patient had then any inquietude, headache, or any such symptom usually subsequent to the fever. The consequence was, that nineteen in twenty-two received immediately relief; the other three had no occasion to take it."

"Encouraged by this surprising success, I next day ordered the opium to be given *during* the hot fit. In eleven patients out of twelve to whom it was thus administered, it removed the headache, abated the fever, and produced a profuse sweat; which was soon followed by a perfect intermission. Since that time I have prescribed an opiate to upwards of three hundred patients labouring under this disease: and I observed, that if taken during the intermission, it had not the least effect, either in preventing or mitigating the succeeding fit; when given in the cold fit, it once or twice seemed to remove it; but when given half an hour after the commencement of the hot fit, it generally gave immediate relief."

Dr. Lind goes on to state that he found the influence of opium more uniform and constant in intermittent fever than in any other disease; and more quick and sensible than that of any other medicine.

Very little need be said in regard to the sweating stage. Up to a certain point the perspiration is to be promoted and encouraged. When the uneasy feelings of the patient have abated, it should be restrained; not suddenly, but with caution. Now the sweating may be promoted by diluents; by keeping the patient in bed, and covered with moderately warm clothes; by sippings of hot gruel, or of hot chicken broth. On the other hand, when the sweating has continued long enough, it may be stopped by drying the patient carefully with towels, changing his linen, and getting him up, out of bed.

It is well to bear all this in mind; but I repeat once more that in agues, such as you are likely to meet with in this country, it is unnecessary, and therefore objectionable, to be *over-busy* during the paroxysm. Whenever the disorder assumes a distinctly intermitting form, the most important part of the practice is that to be employed during the intermissions. Now there are certain general remedies advised for adoption in this period; and there are certain specific remedies. The general remedies are bleeding, emetics, and purgatives. They need not detain us a moment. Blood-letting may be used if there be any apparent tendency to local inflammation, or any marks of severe topical congestion; especially in young and robust subjects. Barring such circumstances, there can be no occasion to bleed your patient in the intermissions.

An emetic given a short time before the expected paroxysm, has been known to prevent its accession; and even has sometimes cured the disease. But we can stop the paroxysms by gentler and better means; so that I should not prescribe an emetic unless I saw symptoms of a foul and loaded stomach.

Purgatives should always be given at the outset. They clear the stomach and intestines of hurtful accumulations, which are apt to impede the beneficial operation of the quina, or of other drugs given to check the disorder. I mentioned in the last lecture my own custom in this matter; viz., to give a couple or three grains of calomel with eight or ten of rhubarb at bed-time; and to commence with the specific remedies the next day.

Of these specific remedies, *bark* and *arsenic* are by far the most certain and important; but a multitude of others have been highly praised for possessing similar virtues. I shall by and by say a word or two about *some* of these, because bark is dear, and arsenic is scarcely a safe drug to be entrusted to the hands of unprofes-

sional persons; and yet it is often expedient, in country places, where agues are rife, to provide the poor with remedies which they may have at hand; and which should both be reasonably cheap, and perfectly safe.

I shall not detain you with any account of the difficulties and objections which were thrown in the way of the *Peruvian bark*, upon its introduction into the *materia medica* about the middle of the seventeenth century. Its use met with the most violent opposition, even from physicians of the highest authority. It was resisted by Stahl and Hoffman; and Boerhaave was never quite reconciled to it. Sydenham, by his example and recommendation, greatly promoted its adoption in this country. All this history is sufficiently curious and interesting, but I have no time for it: and you will doubtless hear it from one of my colleagues. I will merely say that in the *Peruvian bark* we have one of the very few *specifics* that we can boast of possessing: and that, unlike most other highly vaunted substances, so far from falling off from the accounts first given of its virtues, it has acquired in the lapse of time an increase and stability of reputation.

Neither shall I enter at all into the consideration of the qualities of the several species of cinchona; nor of the several principles that may be educed from them; nor of the modes in which the quina even may be best procured. This would not belong legitimately to my province. I must suppose that the professors of chemistry and of *materia medica* have furnished you with the sulphate of quina, which is the only preparation of the bark I intend particularly to notice: and *my* business is to tell you what I know in respect to its employment as a *remedy for ague*.

I may observe, however, that this is a remedy to which we could never have been led by any process of reasoning. It is a matter of pure empiricism. We know nothing of the seat or of the essential nature of the disease; we are equally in the dark as to the *modus operandi* of the quina in curing it; yet our knowledge of ague, upon the whole, estimated in reference to its precision and practical bearing, is more satisfactory than of many other complaints, with the seat and nature of which we are much better acquainted. The group of symptoms is so distinct, that we have no trouble or doubt as to the diagnosis; and experience has taught us a remedy which is all but infallible.

The discovery of quina and its salts formed a great era in the history of the *materia medica*. As far as my own experience goes, the sulphate of quina has quite superseded the necessity for exhibiting any other form of cinchona for the cure of ague. Before quina was unshrouded by the chemist, the bark in substance was the only form in which the remedy could be confidently relied upon; and I am old enough to be aware of the infinite superiority of the salt, over the actual bark. To obtain the desired effect, it was often necessary to give it in such quantities as almost justified Mr. Abernethy's sarcastic way of speaking of it and of physicians. He said the doctors talked of throwing in the bark, as if it were to be pitched into the stomach with a shovel. The sulphate of quina lies in a much smaller compass, and a more commodious form; and it does not cause that insupportable nausea which the woody mass of the powdered bark was so apt to occasion.

I am in the habit of giving two, and sometimes three, grains of the sulphate of quina every four or six hours during the intermissions, to those patients whom I have occasion to treat for ague. This plan has succeeded so well, that I have never been tempted to try any other. I may, indeed, say that I have never known it fail to stop an ague; and to stop it speedily: so that very few paroxysms have occurred after the patient has begun to take the medicine. You may give it in the infusion of roses, which contains a convenient quantity of sulphuric acid to ensure the solution of the sulphate of quina. It changes the colour of the infusion, however, and renders it pinker and opaque. Whether the draught be more or less elegant on that account, I will not take upon me to say; I know that the virtue of the quina is not much interfered with by the change. In private practice, I commonly prescribe twice as many drops of dilute sulphuric acid as there are grains of the quina, with a drachm of the tincture of orange peel, and a drachm of the syrup of the same; completing the draught with water. This I find my patients commonly approve of, except in its bitterness, which, in a solution, nothing can disguise. Or that salt *may* be administered in the shape of a pill: it is best, however, and surest in solution.

A question has been raised, whether this remedy should be given in repeated doses

during the intermissions, or whether one very large dose should be given a short time before the paroxysm is expected. Dr. Home made some experiments on that point in the clinical wards of the Edinburgh Infirmary, some time ago; and he thought that the result was in favour of the plan of giving the bark regularly at short intervals. I have told you the amount of my own experience, which, however, is not very great; nor have I had any severe cases to deal with. I think it not improbable that my patients would have been cured quite as soon if I had given the remedy in half the strength. Dr. Barker, of Dublin, has found small doses equally effectual with large ones; and this is very likely to be the case with *specific* remedies. It would appear, however, that in some quartans it is better to give large doses before the return of the paroxysm. Dr. Elliotson gives large doses just *after* the paroxysm; and then smaller doses during the remainder of the intermission, at regular periods. A great majority of those who suffer ague are poor persons. Of course the first object is to make the cure as *speedy* as possible; the next to make it as *cheap* as possible. So that it is not a matter of indifference, or mere speculative curiosity, to ascertain with how little quina you may cure an ague. I repeat that it has not happened to me to be disappointed, when I have given the medicine in small doses, as already described: which amount to about twelve grains in twenty-four hours; but, then, I suppose my cases have been well behaved and submissive. Dr. Elliotson states that he is continually obliged to give twenty or thirty grains in the twenty-four hours, before he can cure the complaint: sometimes in obstinate quartans, forty-five grains; and he mentions one case in which a scruple of the sulphate of quina, with ten minims of the liquor arsenicalis was given every eight hours in vain, but succeeded perfectly when given every six hours.

It appears, also, upon the testimony of careful observers, that in warm climates larger doses *are* required; and that it takes a *larger quantity*, upon the whole, to repel the complaint. In the aguish tracts of Italy, in the Maremma, small doses are said to be inadequate; and the physicians there are in the habit of giving twelve, twenty-four, or even thirty grains at a time: and in one recorded instance, the dose, in seven days, was got up to 108 grains, before the ague was arrested. The medium dose, in many parts of America, seems to be eight grains.

Respecting any drug, it is desirable to possess some easy test that the amount of it administered has reached the limits of sufficiency and safety;—the limits beyond which it is needless, and might be hazardous, to carry it. Now it has been ascertained that when the quina is given in repeated and gradually increasing doses, it comes at length to affect most persons with peculiar sensations (generally spoken of as sensations of fullness) about the head, and with a sort of buzzing noise in the ears. Sometimes, when thus administered, it reduces, in a remarkable degree, the force and the frequency of the pulse. Very different quantities are requisite to produce these symptoms in different individuals; but whenever the buzzing is experienced, you may conclude that the system is conscious of the full force of the remedy, and that to push it further would be inexpedient.

In this country it has been the custom to exhibit the bark, or its equivalent substitute, in the intermissions only, and to suspend it during the fits. But our American brethren have taught us that this forbearance is unnecessary; that the quina may be given during the paroxysm with perfect safety, and with much advantage; and that, in the severer remittent fevers, the real hazard lies in abstaining from its use, until a comparatively apyretic period may arrive.

The irritability of the stomach is sometimes so great as to make it difficult to introduce a sufficient quantity of the remedy into the system. This difficulty was very much felt at Walcheren: it is in a great measure removed since the discovery of quina. But even the quina sometimes sits ill on the stomach; and often it is scarcely possible to get children to swallow any preparation of bark, on account of its bitter taste. It is an important thing to know, therefore, that this drug has been found scarcely less effectual in curing the disease, when thrown into the rectum. The menstruum in which it is dissolved should not exceed two or three ounces, lest the bowel should reject it. Its expulsion may sometimes be prevented by adding a few drops of laudanum to the enema.

[The quinia may also be administered endermically; from 4 to 10 grains being

sprinkled upon a blistered surface, once, twice or oftener, according to circumstances, in the course of the day. That the remedy will produce its specific effects when thus exhibited we know from experience. — C.]

It is said that bark in substance will sometimes cure the disease when quina fails. I have never witnessed this: but in obstinate cases I would give the quina in the *decoction* of bark.

[It is very certain that the quina, even when given freely and in large doses, will occasionally fail in arresting the disease, and that the majority of such cases will be promptly cured by the bark in substance. This we have seen repeatedly to occur. — C.]

You must not be satisfied with merely stopping the paroxysms. Patients are often too ready to give up their medicine, as soon as the paroxysm has once missed. But the disease is very apt to recur; and it will always be right and prudent to go on with the quina for ten days or a fortnight after the patient *seems* cured, gradually diminishing, after the first week. the amount and the frequency of the doses.

There have been some curious facts observed in regard to the relapse that are apt to take place after the bark or the quina has been omitted. Clark of Dominica, states that if no more of the remedy be taken, in the West Indian ague, than is barely sufficient to stop a fit, and then the bark be suspended, a relapse may take place on the eighth day, in the case of a quotidian; on the fourteenth or fifteenth in the case of a tertian or double tertian; and on the twenty-first or twenty-second in the case of a quartan: thus making (you see) in each type, seven periodical revolutions from the time the fit was suppressed, to the next attack; and the fit was found to return on the proper day, at the same hour at which it would have returned if its course had not been interrupted by the administration of the remedy. Here we have a still earlier glimpse of the abiding periodic tendency, noticed by Dr. Gregory and by Dr. Graves, during the long protracted absence of actual paroxysms. All this is very curious, and inexplicable; but it points clearly to the propriety of continuing the remedy for some time after the disease appears to have vanished.

[The very high price to which quinine has attained of late years, rendering its free use, in cases of fever occurring among those in moderate circumstances, a matter of serious inconvenience, extensive experiments have been made with other of the proximate principles obtained from different varieties of the cinchona, with the view of discovering among them some substitute of less cost and equal efficacy. Of these, the cinchonine, quinoidine, and quinidine present the strongest claims to our notice. The sulphate of chinchonia has been found, from ample experience, to be little inferior, even in the same dose, to the sulphate of quina as an antiperiodic. Both the quinoidine and quinidine are possessed of very decided efficacy, but require to be given in much larger doses than the quinine. — C.]

Arsenic is another substance which has unquestionable and great power over ague. It carries with it these marked advantages: it is efficacious; it is cheap; and it is tasteless. It is well adapted by these qualities for the poor, and for children, and for patients of every age and rank in whom there is much irritability of stomach present; but then it has also the serious disadvantage of being an active poison. One over-dose may be fatal: and even its long-continued use in minute doses leads sometimes to evident and lasting disorder of the health. Arsenic, therefore, is an unsafe remedy to be trusted in the hands of the ignorant. It should never be administered except under the immediate supervision of a medical eye; and even then it requires to be given with much caution. Its bad effects may be very certainly prevented, however, by care and attention; and it becomes a valuable instrument of cure, and should be adopted without scruple, in cases where its operation can be watched, and where the quina does not agree with the stomach, or fails to stop the disease. I often prescribe arsenic for other complaints; but, as I said before, I do not recollect ever having been foiled in removing ague by the sulphate of quina. Some persons are of opinion that relapses are less frequent after the cure by arsenic than after the cure by bark. It would require a large induction of particular facts to make that point clearly out.

When substances, which even in small quantities prove active poisons, are used as remedial agents, it is convenient to have some definite form in which they may be administered at all times, and in all places. The *liquor potassæ arsenitis* of the London Pharmacopœia supplies such a form. This is the form in which arsenic was recommended to the public by Dr. Fowler: and it is therefore sometimes called *Fowler's solution*. It was founded upon an analysis of the *tasteless ague drop*, which had been in considerable repute in some parts of England. The pharmacopœial preparation is an arsenite of potass in solution. There are eighty grains of arsenic in the new or imperial pint, and therefore four grains in an ounce of the solution. Ten minims two or three times a day are a full dose for an adult; and you had better commence with not more than five minims. Ten minims contain one-twelfth of a grain. Twice that quantity has been administered at once; but this ought never to be done except when the system has been gradually inured to the arsenic, and thereby enabled to bear such a dose. It is a good precaution not to give this corrosive substance on an empty stomach.

The poisonous or hurtful effects that we have to look out for, when arsenic has been prescribed, are a peculiar silvery whiteness of the tongue, loss of appetite, nausea, and sometimes vomiting; gripping pain of the stomach and bowels, and diarrhœa; and if the medicine be continued, *fainting* is often added. Other symptoms, less constant perhaps, and less important, are painful and hot tumefaction, suffness, and itching of the face and eyelids, with redness of the conjunctiva, or even a tingling eruption something like nettle rash. These effects may, I believe, be controlled by adding a few drops of laudanum to each dose; but I would rather advise you to suspend the use of the arsenic; or to leave it off altogether. When this is done, the unpleasant symptoms will readily yield to mild laxatives, followed by opiates.

[The arsenical solution is a remedy admirably adapted for the cure of intermittent fever when it occurs in children, to induce whom to take the quina in any form will be found often impossible. When cautiously administered, and its effects are carefully watched, we have never known any disagreeable effects to result from the arsenic, and we have employed it somewhat extensively. — C.]

When the paroxysms continue to recur in spite of the bark, it has been recommended (and I think the plan a good one) to try to stop them by arsenic; and then, the periodic recurrence having been broken, to employ sulphate of quina to prevent a relapse.

These, then, quina and arsenic, are the two sheet anchors to which we trust, in the cure of ague. A host of other remedies, I say, have had their praises sung. I do not intend to enumerate them. But there are a few which I think it right to mention, for reasons already assigned. There is strong evidence of the efficacy of some of them; they are cheap, and easily accessible, and above all, safe; and therefore, in aguish districts, they may with much propriety and benefit be recommended to the poorer classes, or distributed by Lady Bountifuls.

[The ferrocyanuret of iron is certainly a very valuable remedy in cases of intermittent fever. Stokes places it in efficacy after quina and the arsenical solution, and perhaps he is right in so doing; it will, however, often succeed in preventing the recurrence of the paroxysms, given in the dose of six grains every three hours. — C.]

One of these is *willow-bark*; in substance, or in decoction. If this dose cure agues, as it is affirmed to do, it would seem as if Providence had placed the antidote alongside of the poison; for these trees, as you know, abound and flourish in marshy places. The bark of the willow furnishes an alkaloid substance called *salicine*, in which the febrifuge property is believed to reside. Holly leaves, and *ilicine* derived from them, stand in much the same repute in France, as willow-bark and salicine here.

Another curious remedy, said to be very successful, is the *web of the black spider*, which inhabits barns, stables, and cellars. This substance has been tried on a tolerably large scale, and the testimony to its influence in curing agues is very strong. Dr. Craigue has given this account of it. In the year 1760, a number of prisoners from the vanquished squadron of Thurot having been landed in the Isle of Man, Dr. Gillespie, who was practising there, found that many of the agues which came to prevail

both among the prisoners and the inhabitants of the island, obstinately resisted bark and such other remedies as he had recourse to. He was informed, by an old French physician belonging to the squadron, of the alleged efficacy of cobweb, in certain forms of the disease. He therefore made trial of cobweb, and found it to answer admirably. He was successful with it in more than sixty cases of different types, in the Isle of Man, and he had further experience of its utility subsequently in Ayrshire.

After this, the same remedy was tested in the West Indies, by Dr. Jackson, to whom Dr. Gillespie had recommended it. Dr. Jackson's observations were made in the hospital of the army dépôt, in the West Indies, in 1801. Several cases of ague, on which bark, arsenic, or mercury, singly or alternately, had made either a very temporary impression or none at all, were selected for experiment. In four of these cases, two pills, containing each five grains of cobweb, were given at intervals of two hours, commencing six hours before the expected time of recurrence of the paroxysm. The fit did not return. On subsequent trials it was found not only to arrest the course of agues, but to remove various symptoms, such as pain, delirium, vomiting, griping, in ague, and in continued fever, when these symptoms were unconnected with inflammation.

[We have employed the spider's web in this manner in a number of cases, and in many of them found it very promptly to suspend the paroxysms — as effectually, certainly, as the quinia; in a few cases, however, it failed. — C.]

Charcoal is another substance which has been found effectual for the cure of intermittent fevers. You may find an account of it in the tenth volume of the *Edinburgh Medical and Surgical Journal*. It would seem to be especially useful in those cases in which there is a marked disturbance of the digestive organs; nausea, flatulence, hiccup, diarrhoea, or dysentery. It is said generally to cure the complaint by the time two drachms of it have been taken. It may be given in doses of ten or twenty grains, in arrow-root; or with a few grains of rhubarb. If the power of this substance should be confirmed by future observations, a cheap remedy would thus be open to the poor. A clergyman of my acquaintance assures me that he seldom fails to cure agues among his parishioners by administering to them the snuffs of candles, which he takes care to have collected. He does not inform them of what his black powder consists. I presume that its virtue may proceed from the charcoal it contains; unless it is derived from the confidence his flock is accustomed to place in his specific. The very same remedy, the snuff of a candle, is mentioned by Lind.

Piperine, the crystalline salt of pepper, has obtained considerable reputation of late years, as a remedy for intermittent fever. It was largely tried by an Italian physician, Meli; and Dr. Gordini has repeated Meli's experiments at the hospital at Leghorn. The following are the general conclusions at which these physicians have arrived: — 1. Piperine, in doses of six or eight grains, cures intermittents. 2. It is more efficient in powder than in pills. 3. It succeeds in certain cases in which the sulphate of quina fails. And 4. It is more effectual in preventing relapses. I have seen letters from some practitioners in this country, bearing testimony to the power of the piperine. That pepper will cure ague has long been the vulgar belief; and a very popular remedy for the disease is a teaspoonful of pepper in a glass of gin.

I presume that the efficacy of *chamomile* flowers in the removal of intermittent fever is to be attributed to the piperine which they have been ascertained to contain. These flowers had been long in use for the treatment of ague, before the Peruvian bark was discovered; and they are said to have accomplished a cure, since that time, after the bark had failed; but this was before the quina had been educed from it. Heberden advises us to have recourse to chamomile flowers, if the bark should disappoint us. I am always willing to embrace an opportunity of referring to his commentaries, for the exact observations they contain, but above all for the beautiful Latinity of which the whole book is an example. I recommend it strongly to you as being, next to Celsus, the best model you can study for good medical Latin. In reference to the point before us he says, "*Cortex, quanquam rite sumtus, interdum parum efficax est; quo in casu suspicio erit ventriculorum sordibus onustum vim remedii impedire. Itaque vomere oportet; quo facto, febris raro non cedit. Quod si redire perseveret, confugiendum est ad flores chamæmeli, quorum contritiorum scrupulus*

dandus est loco drachmæ cinchonæ, et ad idem præscriptum repetendus. Hos flores, sic sumtos, semel atque iterum profecisse expertus sum."

Several mineral substitutes for the bark, or for arsenic, have been tried and found useful: preparations of *iron* and of *zinc*. From 5 to 10 grains of the sulphate of zinc have been given several times a day; or 3 grains of the oxide of zinc every three hours. Sir Gilbert Blane says that both in the West Indies and in London, intermittents have been cured by the use of this oxide, when they had previously resisted the Peruvian bark. Sir James McGrigor also speaks of it in terms of praise; from what he saw of its effects in the agues of the Peninsula during the war.

Some of the remedies of this mysterious disorder operate upon the mind, or rather upon the nervous system, through the mind. Hence it becomes probable that the *drugs* which have such power over the disease, act also on the nervous system, through the body. And hence also we derive a confirmation of the opinion, that the disease itself is essentially a disease of the same nervous system. Ague has often been cured by the agency of strong mental emotion, such as sudden and great joy, anger, terror, or eager expectation. Thus we read that Quintus Fabius Maximus was cured of an old quartan on the day of a great battle. Strong impressions upon the imagination, producing feelings of disgust and horror, have had the same effect: such as those caused by drinking blood; swallowing a spider gently bruised, and wrapped up in a raisin, or spread upon bread and butter; keeping a spider suspended from the patient's neck in a nutshell, till it dies; and the like. The undoubted success, in many cases, of charms, must be referred to the principle of *faith*. The patient recovers, because he firmly believes in your power to cure him. Dr. Gregory used to relate the case of a patient in the clinical wards in Edinburgh, who, with sundry ceremonies, swallowed some word, written on a slip of paper: the result was, that he had not another paroxysm. And I perfectly recollect having a great awe, when I was quite a child, of my maternal grandmother, because she was reputed to have the power of curing agues by means of some charm. I believe all that she did was to assure the poor people who came to be relieved from their ague, that they should have no more of it *after such a day*; and their implicit reliance upon this prophecy brought about its fulfilment. There seems to be this general principle observable in respect to agues, and to most other diseases which occur in paroxysms, viz., that after they have continued for some time, their further continuance depends more upon the effect of *habit* than anything else: and this habit may be broken by strong impressions made upon the nervous system; and the cure of one paroxysm is often thus the cure of the disease. We have seen examples of the existence of this morbid habit in hysteria, and in some cases of epilepsy. *Cæteris paribus*, that physician will be most successful in these disorders, who is best able to acquire the confidence of his patient, and to gain a powerful influence over his mind.

There is no disease in which the *prophylaxis* is of more importance; but this you will have gathered from the facts which were stated in the two preceding lectures. The disposition to relapse is strongest soon after the disease has been removed; but it generally continues long, perhaps even for life. The late Dr. Macmichael caught an ague many years before his death, by sleeping on a rock somewhere in Greece; and he was ever after subject to occasional attacks of periodic headache, and other aguish symptoms, for which he was obliged to have recourse to bark or arsenic. Of course one essential point in the prophylaxis is the withdrawal of the patient from the influence of the exciting cause; taking him away from the malarious locality. But this cannot always be done; and when it cannot, we must impress upon him those cautions which arise out of the facts ascertained respecting the operation of the malaria upon the human body. Persons who have been exposed to the exciting cause, or who have once had the fever, should in whatever place they may happen to be, avoid over-fatigue, and exhaustion of all kinds; sudden exposure to cold or heat; and the neglect of changing wet clothes; wet shoes and stockings for instance. In a malarious district persons should bear in mind the facts, that the miasmata are much more virulent in the night-time than in the day; and close to the surface of the earth, than in a higher part of the atmosphere. They should refrain, therefore, from going out late in the evening, or early in the morning; and they should rather select the attic than any other floor for their bed-chamber. They who are obliged to go out in the morning in countries where agues are rife, should take care not to go out fasting: a

good hot breakfast should be first taken, or at any rate some moderate stimulus. A crust of bread and a glass of wine, or a small quantity of ardent spirits, will fortify the system against the pestilential miasma. Measures of this kind have been found extremely beneficial in the navy: the giving, for instance, the men a warm breakfast before going out in the morning on malarious shores in boats, whatever the hour of starting might be. Generous diet, and a fair allowance of fermented liquor, are proper also for all persons in aguish countries. The late Dr. James Gregory used to mention in his lectures an anecdote in point told him by his father. The elder Dr. Gregory studied at Leyden, under Boerhaave; and twenty-four other English students were living there at the same time: that is, they were called English, on account of their common language, but they were in fact composed of English, Irish, Scotch, West Indians, and Americans. The celebrated John Wilkes and Charles Townsend were among the number. These twenty-five students lived a good deal together; in truth they were *cut*, as the phrase is, by the Dutch, for some raffish behaviour on their parts. However, of the twenty-five, one only was a water-drinker. The other twenty-four each drank a bottle of claret daily; and the water-drinker, and he alone, fell ill of ague there.

Persons who have recently become residents in aguish districts, or who even happen to be travelling through them, would do well to take one or two moderate doses of quina daily, by way of safeguard. Strong evidence has been brought forward of late, by Dr. Bryson and others, to show that its prophylactic power is no less marked and sure, and therefore no less valuable, nay even more valuable, than its curative. Under these circumstances of exposure, warm stomachic laxatives are to be preferred to cold aperients, such as the neutral salts, for due regulation of the bowels.

There is just one more expedient which I would suggest as not unlikely to afford complete protection to those who are of necessity exposed to the malaria; and it is, that they should wear an *orinasal respirator*. It is possible that as a breeze is filtered of the poison which was mingled with it, by passing through a dense mass of foliage, so, on a smaller scale, the air inspired in breathing may be strained and purified, and rendered harmless, in its transit through the sieve-like structure of Mr. Jeffreys' ingenious instrument. The principle of the suggestion is not new; but this mode of applying it has not, so far as I know, hitherto been tried. It is said that by surrounding the head with a gauze veil, or conopeum, the action of malaria is prevented; and that thus it is possible even to sleep in the most pernicious parts of Italy without hazard of fever. Dr. Maceulloch states that in Malta, and elsewhere, this belief is universal: and hence the popular practice of covering the mouth and nose with a handkerchief in the morning on going out, or in other suspicious circumstances: a practice (he observes) the efficacy of which is attested, as far as popular belief can attest anything. Can it be the moisture which accumulates upon the handkerchief from the breath that confers the protection? Under inevitable exposure to the malaria might not Dr. Stenhouse's *charcoal* apparatus, used during the acts of inspiration only, effectually arrest, and perhaps destroy, the entering poison?

[BILIOUS REMITTENT FEVER. — With the exception of the intermittent, the most common form of fever prevalent in the middle, southern, and south-western sections of the United States, is the remittent, or, as it is generally denominated, from the evidences of more or less derangement of the hepatic function by which it is attended, the bilious remittent, or, simply, bilious fever. It constitutes the summer and autumnal endemic of many of our states, and even in those which are exempted from its annual occurrence, it occasionally prevails, during seasons of unusual heat and dryness, sporadically, or as a severe and widely-spread epidemic. It is this form of disease to the attack of which individuals, from the cold and temperate sections of our Union, are so peculiarly liable on removing to those localities where it is endemic, or on visiting them during the summer and autumn. The bilious remittent fever is not peculiar to the United States; it prevails extensively in the southern portions of France and Italy, and other parts of the south of Europe, in Africa, and in the East and West Indies: it is in fact the endemic of the paludial districts of all hot climates. A high degree of atmospherical temperature has a very marked influence in the production of this form of fever. It may act either by eliminating an æriform morbid matter, or by predisposing the system to the action of those morbid causes by which

it is constantly surrounded. The prevalence, as well as the violence of the disease, is almost invariably in direct proportion to the heat of the season, while, in many of the more northern states, where the disease is not one of ordinary occurrence, it will nevertheless prevail, during a summer of extreme heat, often to a considerable extent—and marked, occasionally, by symptoms of extreme violence; being limited, however almost exclusively to those situations, noted in other seasons for their insalubrity, or in which the causes of disease are ready to be developed upon the occurrence of any unusual degree of atmospherical heat.

Notwithstanding the bilious remittent fever can scarcely ever be mistaken by the least experienced practitioner, it still exhibits considerable diversity in many of its phenomena in different seasons and localities, and often in different individuals. While, in many cases, the remissions are well-marked, approaching in some to almost a complete intermission, in others the remissions are so slight that the fever has nearly a continued form. There are always, however, certain prominent symptoms, invariably present, an attention to which will lead at once to an accurate diagnosis:—These are, gastric irritability, a sense of oppression and distress at the epigastrium, pain of the head, back, and limbs, and the great prostration of strength early exhibited by the patient.

Bilious remittent fever is closely allied in its nature, the localities in which it chiefly prevails, and in many of its phenomena, to intermittent fever, of which by many it is considered as a mere modification. It is presumed, and with much plausibility, that “a more intense operation of the same morbid cause required for the production of intermittent fever engenders remittent,” and that “the more violent the latter, the more remote is its character from that of intermittent; or, in other words, the less perceptible the remissions.” That a more powerful action of the morbid cause is demanded for the production of remittent fever, is supposed to be indicated “by the circumstance, that, when periodic fevers are prevailing in certain countries, the permanent residents are often observed to have the disease in the form of ague only, and the mortality among them is small; while strangers, unhabituated to the climate and its diseases, suffer from remittents, with a proportionably greater loss of life. In more sickly seasons remittents will be the prevailing form among both classes of persons, but strangers are more violently affected, and the mortality among them is greater. Its affinity to intermittent is shown, too, by the tendency which it has to pass into that form, and, inversely, by the proclivity of ague to assume the remittent type.” (BROWN; *Cyclopædia of Pract. Med.*)

There is a very striking analogy between the milder and more ordinary form of the bilious remittent fever, in its course and progress, and the periods of a double tertian ague. Although the exacerbations occur daily, yet there is almost always a very manifest aggravation of all the symptoms on the odd or alternate days. When the disease assumes, as it does occasionally, a quotidian type, the exacerbations generally occur several hours earlier than those of the double tertian form—the former happening usually about nine or ten o'clock, and the latter not until towards noon, or an hour or two later.

The milder and more simple form of bilious remittent fever is generally preceded, for some days, by listlessness, languor, a bitter taste in the mouth, nausea, aversion from food, an indescribable uneasiness and sense of fulness about the epigastrium, sometimes costiveness, and, very generally, more or less pain and heaviness over the eyes. The attack is usually ushered in by a slight chill, or merely by a sense of coldness, particularly about the back, which, after one or more hours, and often sooner, is followed by increased heat of the whole surface—the skin becoming, at the same time, dry and constricted, the face flushed and turgid, the eyes red and suffused, the respiration hurried and uneven, the pulse quick and frequent, but rarely tense; there is great prostration of strength, with considerable restlessness and watchfulness. The patient complains of pain and a sense of fulness, weight, and tension of the head, pain of the back and of the extremities, particularly of the calves of the legs;—and of a sense of weight or oppression, and often of pain at the epigastrium, which part generally exhibits more or less tenderness upon pressure, even when no pain is complained of. The stomach is more or less irritable—some cases being attended with distressing nausea, while in others, everything swallowed is instantly rejected. Spontaneous vomiting is a not unfrequent symptom—it is often present from the com-

commencement of the attack, but more generally it does not set in until the second or third day, or even later; the matter vomited being of a bitter taste, and of a yellow, greenish, or bright-green colour. The tongue is usually moist, red at the sides and edges, and coated on its upper surface with a whitish, light-brown, or yellowish fur, which often acquires considerable thickness. There are usually considerable thirst, a costive state of the bowels, and a diminished amount and increased coloration of the urine; and, after the disease has continued for some days, the skin acquires a yellow tinge, which is sometimes very decided, and extends to the adnata of the eyes. The exacerbation lasts from eight to twelve hours, when a gradual abatement of all the prominent symptoms takes place, and often a slight moisture breaks out upon the surface, and the patient falls into a refreshing sleep; more generally, however, the skin continues dry after the heat has declined, and the patient during the remission continues restless, uneasy, and disinclined to sleep. The duration of the remission varies with the violence of the attack; gradually, however, the heat of the surface increases, and an exacerbation of the fever follows, marked by the same degree of intensity as the former one, or even by increased violence.

All the preceding symptoms, in an aggravated degree, with long-continued exacerbations and less distinct remissions, mark what has been termed the highly inflammatory form of the disease. During the exacerbation the skin is intensely hot, the eyes are suffused, of a muddy, yellowish hue, and often dull and languid; there are intense pain, and a sense of insupportable weight and tension of the head; aversion from light and sound is ordinarily present, and occasionally delirium; there are great thirst, and a feeling, often almost insupportable, of oppression at the chest; the respiration being quick and laborious, frequently irregular; the pains in the back and extremities are often of great severity; the pulse is quick, frequent, and more or less tense; occasionally it exhibits some degree of irregularity; the nausea and vomiting are generally peculiarly distressing — the matter discharged being a thick ropy fluid, of a yellow, darkish-brown, or green colour; the bowels are costive, or if open, discharge, with tenesmus and griping, a thin watery fluid: when evacuations are procured by appropriate means, they are large in quantity, dark, slimy, tenacious, and offensive. There is always an intolerable sense of oppression or constriction at the epigastrium, accompanied by a degree of tenderness which renders the slightest amount of pressure insupportable — or a severe pain and burning, attended in many cases with great nausea, and frequent ineffectual efforts to vomit, are experienced. There is great restlessness, with jactitation, and continued watchfulness. In the course of the disease, the skin acquires, most generally, a brownish, bronzed, or more frequently, a deep yellow tinge, which is particularly marked upon the face and breast. A symptom mentioned by Rush, as generally present in cases of bilious remittent — namely, a seratus, or constant hawking and spitting of a small quantity of tough, glairy matter — we have repeatedly noticed.

The succeeding exacerbations are marked by an increased violence of all the predominant symptoms of the disease, and unless the intensity of the fever is relieved by an appropriate course of treatment, the powers of life gradually sink; the surface, at length, becomes cool, and covered, generally or partially, with a cold clammy sweat; the pulse small and weak; the tongue covered with a dark, thick coating, and occasionally dry and chapped; the respiration short, quick, and difficult; the abdomen sometimes swollen and tympanitic; stupor or coma often ensues; not unfrequently, repeated, and at length involuntary, discharges take place from the bowels, of a dark, offensive matter, and finally death ensues.

In the milder forms of the disease, or when it has been from the commencement of the attack subjected to an appropriate treatment, instead of an increased violence in the phenomena of each succeeding paroxysm, there is less decided heat of the surface, the pulse becomes slower and less frequent, there is less gastric distress, less pain and tenderness of the epigastrium; less pain of the head and back; the exacerbation is of shorter duration, and as it declines, the skin becomes softer and more moist, the tongue less coated, the countenance more cheerful, and the patient obtains often several hours of quiet and refreshing sleep; the remissions are more distinct, and of longer continuance, until finally a complete intermission occurs, followed by a state of convalescence — which is usually protracted.

There generally takes place in the milder and uncomplicated forms of bilious

remittent, a distinct exacerbation, followed by an evident remission, once in every twenty-four hours: but in the more violent and decidedly inflammatory form, the remissions, as we have already remarked, are so short and slight as almost to pass unnoticed, and hence the inflammatory bilious fever is described by many writers as a continued fever.

The duration of the disease varies with its degree of violence and its simple or complicated character—it may terminate in a few days or run on for several weeks—but its usual duration is from nine to fifteen days. It is not uncommon, Dr. Dickson, of South Carolina, remarks, especially among the most perfectly acclimated adult natives resident in malarious localities, and strangers long familiarized to these, to find bilious remittent fever of a very protracted duration; “the patient sinking, after the tenth or twelfth day, into a low form, resembling the less severe grades of typhus, and hence obtaining among us the designation of the typhoid stage of bilious fever. Here the well-marked lines which separate the period of exacerbation and remission, are almost effaced; the characteristic periodicity almost obliterated; the fever degenerates nearly into the continued type, and the patient, in the language of the older practitioners, ‘wades through’ the attack with no definitely regular changes observable from time to time, until, by the success or failure of our efforts in his behalf, he recovers or is lost. The pulse is small and chorded, the tongue throws off its fur, and is smooth, red, and dry, or smeared over, like the teeth and lips, with foul sordes; the stomach loses its irritability, and the vomitings cease; the stools are dark or even black; meteorism occasionally shows itself; there is muttering delirium, or disposition to heavy stupor and coma; the countenance is dull and inexpressive; muscular languor and great debility ensue, with nervous tremors on motion, and perpetual subsultus tendinum.” Dr. Dickson has known cases of this kind protracted, in three instances, to thirty, thirty-five, and fifty days, though the average, he observes, would scarcely reach beyond fifteen or twenty.

A careful analysis of the phenomena of bilious remittent fever shows, very conclusively, that the organs chiefly affected are the liver and stomach, and the results of post-mortem examinations confirm the accuracy of this deduction. In many cases, it is true, the symptoms during life, and the lesions detected after death, indicate more or less affection of the lungs or brain; but this latter is to be viewed as an accidental complication, and not essential to the disease. Basing our conclusions upon the investigations of Dr. Stewardson, (*American Journ. Med. Scienc.*, April, 1841, and April, 1842,) which are confirmed by the subsequent observations of Dr. Swett, (*ibid.*, Jan., 1845,) and correspond in many particulars with those of Mr. Twining (*Diseases of Bengal*, chap. v.), a morbid condition of the liver would appear to be invariably present in remittent fever—to be indeed diagnostic of the disease. It is nevertheless very certain that few cases of billous fever, of any intensity, occur without being attended also by indubitable lesions of the gastro-enteric mucous membrane—the evidences of which are very generally detected in those who die of the disease. In many cases a morbid condition of the liver is the principal lesion detected after death, while in others lesions of the gastro-enteric mucous membrane are the most prominent; in general, however, indications of disease in both these organs are sufficiently well marked in the same case. It has been proposed to distinguish the fever, according as the phenomena of hepatic or gastro-enteric disorder predominates, by the terms *hepatic* and *gastric*. *Hepatic remittents* being characterized by intense febrile heat; violent pain of the head; fulness and tension of the right hypochondrium, with pain and pulsation of this part and of the epigastrium; excessive irritability of the stomach; frequent and forcible vomiting, the ejections being without any trace of bile; a clean state of the tongue in the early stages; a decidedly yellow colour of the skin and adnata of the eye; great torpor of the bowels, until towards the decline of the disease, when a copious discharge takes place from the bowels of a dark or pitch-like tenacious matter, which may be considered as in some degree critical.

Gastric remittents are distinguished by a bitter taste in the mouth; great thirst, with a craving for cool and acidulated drinks; frequent vomiting of a green or dark-brown fluid; total loss of appetite, and generally disgust for every kind of food; a feeling of great weight and anxiety at the præcordia; pain and tenderness, chiefly at the epigastrium; intense pain of the loins and knees, and soreness of the calves of

the legs; severe and constant pain of the forehead; the tongue coated in the centre with a thick layer of yellowish mucus, and red at the sides and tip; the remissions distinctly marked; bowels costive, or when discharges from them take place, these are thin and watery, and often attended with griping and tenesmus: in the course of protracted cases the stools, not unfrequently, consist of a reddish fluid resembling the washings of meat. In the progress of the disease, the tongue becomes dry, cracked, and covered with a dark-brown or blackish crust; upon the separation of which the tongue presents a smooth, shining, and red surface. In the advanced stage, there is often retention of urine, difficulty of swallowing fluids, meteorism of the abdomen, &c.

Although we frequently meet with cases in which the predominance of hepatic or of gastric disorder, but especially of the first, is thus strongly marked; nevertheless, in the general run of cases, there is a complete blending of the two sets of phenomena.

There is one form of bilious intermittent still to be described, with which the experience of the last ten years has made the practitioner of the southern and southwestern portions of the United States, unhappily, too well acquainted, under the denomination of *congestive fever*. "In certain localities, indeed," remarks Dr. Dickson, "the ancient inflammatory features of malarious endemics seem to have disappeared, and to have become supplanted by the more hideous and pestilential modification thus entitled."

The form of the disease to which we allude is marked by a diminished temperature and decreased sensibility of the whole surface of the body—the skin being, at the same time, soft, contracted, and often clammy, or wet with a copious perspiration. When a partial reaction takes place, the heat is never considerable, and it is often confined to particular parts of the surface. There are considerable and universal lassitude and debility; the head is confused and affected with vertigo, and sometimes with a deep-seated pain, or a sensation of oppressive weight or tension; the eyes are heavy, suffused and dull; the countenance is haggard, and the face pale, and of a dingy, muddy appearance; the pulse is small, frequent, and indolent, or struggling, compressible and variable; the tone of the voice is often changed, the articulation being slow and drawing, or imperfect and stammering. The respiration is anxious and laborious, with frequent sighing. The tongue exhibits, at first, but little change, but soon becomes dark-brown or black, especially in those cases in which the earlier stages of the disease have been marked by some degree of excitement. The stomach is occasionally irritable; the epigastrium and right hypochondrium are tender upon pressure, and more or less tumid; the bowels are torpid, and when stools are procured, they are dark-coloured and offensive, and often attended with tormina and tenesmus. The mind is generally dull, indifferent, or confused, from the commencement of the attack, and, in the progress of the disease, sinks into a state of more or less complete stupor, or of low muttering delirium. The remissions of the fever in the congestive form are not well marked, or rather, there is an entire absence of the febrile exacerbations and remissions, the phenomena of the disease presenting but little other change than a rapid or gradual augmentation in intensity. In fatal cases, death, which may take place between the fifth and fifteenth days, or even later, is often preceded by hieup, subsultus tendinum, involuntary stools, hemorrhage from the stomach or bowels, petechiæ, &c.

The congestive form of bilious remittent fever may attack suddenly, when it is apt to assume a peculiarly malignant form, and to terminate rapidly in death; in many cases, however, it is preceded by the same symptoms as the milder and more open forms of the disease. In the more violent attacks of congestive fever, "the system seems," to use the words of Dr. Dickson, "to sink at once prostrate before the invasion or exacerbation, which can scarcely, at times, be called febrile. Reaction, to use our technical phrase, does not take place, or very feebly, if at all. The skin is cold, and covered with a clammy sweat, as in the collapse of cholera; the pulse is weak and fluttering; the stomach is very irritable, with frequent and painful, but usually ineffectual, efforts to vomit; the countenance is shrunken, and pale or livid; there is often low muttering delirium, with shivering and fainting. In some cases, no complaint is made, a lethargic insensibility seeming to oppress the patient; in others, the most extreme anguish is endured by the miserable sufferer, who in his agony often

utters groans or loud cries. The vital powers are speedily and irrecoverably exhausted by the recurrence of a few such exacerbations, although the remissions in this class of cases are usually well defined, and full of transient relief and hope. The third, fourth, or fifth return of the train of symptoms delineated, for the most part, puts an end to the distressing scene."

The phenomena of congestive fever are evidently the result of defective innervation, and an impeded action of the heart and lungs; the blood, imperfectly decarbonized, accumulates in the interior organs, and thus prevents the full and regular exercise of their functions. The impression of the morbid causes by which the disease is produced is, in all probability, made primarily upon the nervous centre, and by depressing the energy of its action, gives rise to all the other phenomena which characterize this form of fever.

The propriety of denominating these cases of congestive disease bilious remittent fever, when they frequently run their course without exhibiting the slightest indication of febrile reaction, has been doubted by some. They are, however, produced by the same causes as the bilious fever, and, when the congestion is early removed, the case often assumes all the characteristics, and runs the same course as in the ordinary form of bilious fever, showing that the phenomena of the latter were merely masked or suspended by the congestive state of the principal vital organ.

The convalescence from an attack of all the forms of bilious remittent fever is always protracted. Relapses, from slight irregularities of diet or too early exposure, are not unfrequent. After severe attacks, the hair often falls entirely off, and is only slowly and imperfectly renewed, or the patient remains permanently bald. The functions of the stomach and alimentary canal, generally, are imperfectly performed for a long period after recovery, and require the utmost circumspection on the part of the patient to insure their complete restoration. Jaundice is a very frequent consequence of bilious remittents. This, Dr. Dickson states, "was noticed generally in the summer and autumn of 1824; very few patients recovering from the fever in that year without becoming icteric. Nor is it rare to meet with hepatic enlargement and induration, attended by a long succession of sufferings from visceral obstructions and mechanical impediments to the performance of the abdominal functions, and to the transmission of the abdominal circulation. Hence ascites and anasarca, and hence diarrhoea and dysenteries called hepatic, and occasionally melæna and true intestinal hemorrhage. The spleen suffers from remittents of malarious origin, as from their kindred intermittents, though not by any means so uniformly, sometimes undergoing a permanent and inconvenient increase of size or hypertrophy."

With the pathological anatomy of remittent fever we are but imperfectly acquainted; very few facts in relation to it have been recorded, and of these few many are loosely and imperfectly detailed, while those upon the accuracy of which reliance can be placed, are derived from too limited a series of observations to allow of any positive general conclusions being based upon them. That, however, the stomach and liver are the organs in which indications of disease are the most uniformly detected, all the facts in our possession very clearly prove, although the exact nature of the morbid lesion is not very clearly made out. "The closest attention to clinical observations," remarks Mr. Twining (*Diseases of Bengal*, chap. v.), "as well as the result of post-mortem examinations, convince me, that remittent fevers in Bengal, *are invariably connected with local congestions*, which often run rapidly into inflammations, attended with much interstitial effusion. The seat of these local affections is found principally in the stomach, intestines, cellular structure about the duodenum, and at the root of the mesocolon, more especially where it passes across the spine. The principal disease is also often found in the spleen, liver, brain, or lungs." Dr. Gerhard, of Philadelphia, maintains, as the result of his observations, that the anatomical character of the more severe forms of intermittent fever is to be detected in the spleen, liver, and stomach; the bilious and remittent fevers being "probably referable to the same class as the malignant remittents." These conclusions are confirmed by the observations made by Dr. Stewardson, in the Pennsylvania Hospital; by those of Dr. Swett, made in the New York Hospital; and by the results of dissections in single cases, as reported by Dr. Howard and others. Dr. Boyd describes the indications of disease, after death, in the bilious fever of Minorca, as occurring in the brain, lungs, liver, and stomach; the liver, he states, was in most instances enlarged,

often inflamed, with its inferior margin livid; the gall-bladder distended with viscid bile. The stomach and intestines were often inflamed; the villous coat being of a dark colour.

The appearances in the stomach are variously described; but in general, they are stated to be injection, with increased redness of the mucous membrane—sometimes thickening and occasionally softening of that membrane. In many instances, the same appearances are described as being present in the duodenum. The glands of Brunner, in this intestine, were, according to Dr. Stewardson, “developed in a remarkable manner,” in the cases examined by him; a similar development did not, however, occur in the fatal cases which fell under the notice of Dr. Swett.

In all the dissections made by Drs. Stewardson and Swett, and the one reported by Dr. Howard, the liver was found to be flabby, of a bronze colour, the two substances composing the organ being blended together in such a manner as to be scarcely distinguishable. The spleen was much enlarged and softened. The peculiar condition of the liver, just described, Dr. Stewardson believes to constitute “the essential anatomical character” of remittent fever: he thinks it highly probable that the same alteration of the liver will be found to exist in intermittents which prove fatal in their early stage; these and intermittents being, in his opinion, essentially the same disease.

Drs. Gerhard, Stewardson, Swett, and Howard, never detected in any case, after death from remittent fever, the glands of Peyer, and the other intestinal follicles, in a diseased condition. Although we believe that these parts will generally be found in a perfectly healthy state, nevertheless, it is certain that cases do occur, particularly of the more protracted forms of the disease, in which the evidences of follicular inflammation of some portion of the small intestines, terminating occasionally in ulceration, especially of the glands of Peyer at the lower end of the ileum, are present after death. Such cases are referred to by Dr. Geddings, of Charleston, Drs. Stevens and Vache, of New York, Dr. Harrison, of Cincinnati, as quoted by Dr. Dunglison (*Practice of Med.*, 2d ed., vol. ii. p. 450). A diseased condition of the glands of Peyer is stated to have been present also, in all the cases examined by Dr. Richardson in the New York Hospital, in 1840, (*Dr. Swett, American Journal Medical Sciences*, January, 1845;) and the same lesion was noticed by Dr. McWilliam in the African remittent fever.

The indications of congestion and of inflammation so frequently met with in the brain and lungs, point out the tendency there exists in remittent fever to disease of those organs, but they are not invariably present, nor are they essential to the disease.

In cases of congestive intermittents, the anatomical lesions are the same as those described above, excepting, that when death takes place previously to the occurrence of complete reaction, there is very generally extensive hyperæmia of the brain, lungs, liver, and spleen.

The diagnosis in bilious remittent fever will depend, in a great measure, upon the character which the disease presents in different localities and in different years, as well as upon the constitution, and other circumstances connected with the individuals attacked by it. In the milder forms of the disease, with distinct exacerbations and remissions, and no marked tendency to disease of the more important organs, particularly when these occur in persons of temperate habits, and of constitutions neither broken down on the one hand by previous disease, fatigue, or the depressing passions, &c., nor, on the other, marked by undue plethora, or a tendency to congestive or inflammatory affections of the central organs; by a judicious treatment, early commenced with, a favourable result may very generally be obtained. Even the more strongly marked inflammatory form of the fever seldom terminates fatally when vigorously treated from its onset. The congestive or malignant form of the disease is one in which the prognosis is much more unfavourable. In epidemics of congestive bilious fever the mortality is often truly appalling. Remittent fever, generally speaking, attacks with less severity, and is more readily controlled in those acclimatized, as it is termed, to the districts of country in which it occurs as an epidemic—that is, persons who, having passed through the disease, continue to reside in those districts. A stranger, recently arrived, particularly from a northern climate, and if a high liver, or of intemperate habits, or whose occupation subjects him to exposure and fatigue, is not only more liable to be attacked than the former class of individuals, but in such a case the disease will usually be marked by greater severity, and be more liable to ter-

minate fatally. The favourable symptoms, in individual cases, are, the mildness and comparative shortness of the exacerbations, the completeness and long duration of the remissions, particularly when the latter are accompanied by a free and diffused perspiration, and the patient falls into a quiet and refreshing sleep; the postponement of the succeeding exacerbations beyond their anticipated periods; the diminution or removal of the tendency to disease of particular organs; the occurrence of more regular and healthy discharges from the bowels; the tongue becoming cleaner and the pulse slower and less frequent, &c.

The bilious remittent fever, as we have already remarked, is a disease of hot climates and of the season of greatest heat; thus, while it constitutes the summer endemic of the southern portion of our Union, it seldom occurs in the middle and northern states, excepting during those summers that are marked by an unusual elevation of temperature; and here, as well as in the places where it prevails endemically, it ceases as the winter approaches. Whether the fever can be produced simply by exposure to a high degree of atmospherical temperature, is a question that has been frequently raised; and while many maintain the affirmative, others as positively assume the negative. It is very certain, however, that the long-continued action of excessive heat upon the body, by predisposing it to the action of other morbid agents, will, in this manner, often bring on an attack of bilious fever, independently of malarious influences. Thus, nothing is more common than for the disease to immediately occur in those who, after exposure to the midday sun, or after many hours of severe labour in intensely hot weather, allow their bodies to become chilled by sleeping on the ground in the open air after night; by neglecting to change their clothing when they become wet by a shower of rain or other cause; or, while the perspiration is running in streams from every pore, by throwing off a portion of their clothing, and sitting or lying in a draught of air, particularly after sundown. But while many of the sporadic cases are produced in this manner, and the same species of imprudence is a common exciting cause of the fever when it prevails as an endemic or epidemic, a large number of incontestable facts would seem to prove that its more common cause is a poison produced by the action of high degrees of solar heat upon such portions of the earth's surface as are ordinarily covered or soaked with water, when these are accidentally laid bare, or rendered dry by long-continued heat and drought. The presence of substances, whether vegetable or animal, liable to decomposition, is to be included among the causes capable of generating bilious fever in hot climates, and in the more temperate climates during summers of unusual heat. In our larger cities the disease always prevails most extensively, and in its more malignant forms, in the most confined and filthy districts, to which it is often entirely confined; or, when it makes its appearance in other parts of them, it can generally be traced to the presence of some local cause of infection. In Philadelphia, where bilious remittent fever was formerly a common disease of the summer and early autumnal months, it is now of rare occurrence, excepting in its mildest form; and this disappearance of the disease from our city is to be ascribed more to the better construction and cleanliness of our docks, and the greater attention which is paid to the paving, draining, and sewerage of our streets; to the filling up of the numerous ponds which formerly existed in and about the city, and to the preventing any mass of putrefiable materials from being stored in the city proper and surrounding districts, than to any very decided diminution in the temperature of our summers.

In the treatment of bilious remittent fever, the first and most important question that presents itself is, the propriety of direct depletion by the lancet. This must be determined solely by the character of the symptoms and condition of the patient in each case. In the more decidedly inflammatory cases, when the exacerbation is well-marked and prolonged — when it is attended by a hot skin, flushed and turgid face, severe pain of the head and back, great oppression about the præcordia, and a firm or chorded pulse — and when the intermissions are short and imperfect — more particularly in cases occurring in young, robust, and plethoric habits, and who have but lately arrived from a colder climate, there can be no doubt of the importance of blood-letting. In such cases a vein in the arm should be opened at the early period of the attack, and a sufficient amount of blood drawn off at once to reduce the violence of the exacerbation: one sufficient bleeding at the onset of the disease is far more efficacious and better adapted to prevent local determination than the repeated detracti-

of small quantities of blood during its course. A repetition of the bleeding will seldom be demanded when the first operation has been carried to a sufficient extent; should, however, the succeeding exacerbation be marked by any degree of violence, we should not hesitate again to resort to the lancet; but the loss of a less amount of blood will be required to reduce the excitement than in the first instance. If direct depletion by the lancet has been neglected in the early stage of the disease, it will seldom be admissible subsequently—or, should symptoms seem to demand it, it must be employed with the utmost caution, and only to a moderate extent.

That numerous cases of bilious fever occur in which venesection is altogether unnecessary, is unquestionably true; in those, however, that are marked in their early stage by a high degree of arterial excitement, and a tendency to local hyperæmia or inflammation, the remedy cannot be dispensed with without danger to the patient. When timely employed, we have repeatedly been surprised at the very great and prompt relief produced by it—the violence of the exacerbations becoming reduced, the intermissions more complete, the skin cooler and more relaxed—the pain of the head relieved—the bowels readily acted upon; and a state of calmness, even of refreshing sleep, will often succeed to the previous restlessness and distress.

Local blood-letting is a remedy which is, perhaps, more generally demanded in bilious remittent fever than bleeding from the arm. In all cases attended with intense pain of the head, throbbing of the temples or delirium—or with pain or decided tenderness of the epigastrium and right hypochondrium, or with pain, and a sense of tightness or oppression about the thorax—in conjunction with general bleeding, or where this has not been judged necessary, the application of leeches or cups in the neighbourhood of the local suffering, in numbers proportionate to its intensity and to the age and condition of the patient, will invariably be followed by decided and, generally, permanent relief. The very great suffering which many patients experience from pain in the back and loins, we have, in repeated instances, known to be completely relieved by cups applied along the spine.

In regard to the propriety of cathartics in the treatment of bilious remittent fever, there is a much greater unanimity of opinion than in relation to blood-letting. There are few, if any cases, in which their operation will not be found beneficial, by removing from the intestines the vitiated secretions with which they are often filled—procuring regular stools, and by assisting to reduce the congestion of the portal system, and thus restoring the healthy functions of the liver and digestive organs generally.

It is not, however, every purgative from which good effects are to be anticipated in bilious fever. Under the free employment of certain cathartics the patient will often be found gradually to become more and more debilitated, and finally to sink into a state of stupor, with suffused eyes, weak, fluttering pulse, and other symptoms of extreme exhaustion. In such cases it will be found that the discharges from the bowels consist of a thin, serous fluid. Under the employment, however, of such purgatives as produce consistent, viscid, and dark-coloured stools, the indications of improvement in the symptoms of the disease are often prompt and striking. Calomel is probably one of our best cathartics in this disease. It may be given either alone, in a full dose, and followed by occasional doses of castor oil—senna tea—calcined magnesia—or laxative enemata; or the calomel may be combined with rhubarb, or jalap; or, what is frequently a more effectual plan, a full dose of the calomel administered at first, and then, every three or four hours, according to the effects produced, moderate doses of the blue mass and rhubarb, with the addition of a small portion of ipæcacuanha. By these means we shall generally succeed in freeing the bowels of the dark-coloured, viscid matter with which they are often loaded, and procuring more regular and healthy stools—after which, an occasional dose of the milder laxatives will alone be required.

In all cases of bilious remittent fever attended with a hot and dry skin, the application of cold to the surface, either by sponging it with cold water or cold water and vinegar, or by the application of cold water in the form of affusion, will have the effect, while it reduces the morbidly increased temperature, of relaxing the skin, and promoting perspiration, and in this manner shortening the exacerbations and inducing a complete intermission; even the exposure of the body to a current of cool air—by throwing off the clothing and opening the doors and windows of the patient's chamber, will in most cases be productive of the most beneficial effects. The mere

immersion of the hands and arms in cold water, by carrying off a portion of the morbid heat and allaying thirst and restlessness, will be found grateful to the patient, who not unfrequently will fall immediately afterwards into a refreshing sleep. Whenever the exacerbation is attended by intense heat of the surface and other symptoms of violent excitement, it is from the application of cold water to the surface by affusion or sponging that the most prompt and permanent advantage is to be obtained. Dr. Dickson ranks it among the most efficient of our febrifuge measures — far above the lancet, both in the extent of its adaptation, and in its degree of specific utility. All that we can hope or anticipate from blood-letting may be obtained, in the majority of cases, from the use of the cold bath, while the latter possesses this striking and obvious advantage, that we can repeat it as often as the symptoms are renewed that require its employment. The local determination which it controls most promptly, he very correctly remarks, is that to the brain, indicated by the headache, flushed face, red eye, delirium, &c., with a full, hard, bounding pulse. In such cases, the patient being seated in a convenient receptacle, a large stream of cold water should be poured over his head and naked body from some elevation, and continued until he becomes pale, or his pulse loses its fulness, or his skin becomes corrugated and he begins to shiver; he should then be dried and placed in bed, with just so much covering as he feels to be comfortable, the chamber being, at the same time, fully and freely ventilated; or without removing the patient from the bed, he may be supported in a leaning posture over its edge, and the cold water poured from a pitcher over the vertex.

The application of cold water to the surface is proper only when the temperature of the latter is considerably and permanently increased over the whole body, and at the same time the surface is perfectly dry. When the skin is cool or covered with moisture, the use of the cold water is inadmissible; it is also of doubtful propriety when there exists a decided tendency to hyperæmia or inflammation of the lungs, or in cases attended with diarrhœa. Its repetition is forbidden when it has occasioned a protracted chill or rigor; or the patient continues to feel cold or uncomfortable after its use.

The testimony of Dr. Dickson in relation to the curative powers of cold water applied to the surface in the bilious remittent fevers of the south is strong and pointed, and is fully borne out by the experience of physicians of other portions of the United States and of Europe, who have extensively employed it in the disease under consideration. Equally important with the external employment of cold water is its use, internally; — allowing the patient to drink freely of cold, or even iced water or iced lemonade, is not only highly grateful to him, but it tends to diminish the morbid excitement, relax the skin, and promote a free and uniform diaphoresis.

Diaphoretics, particularly a combination of tartar emetic, nitre, and calomel, have been recommended and highly extolled by many practitioners, in the inflammatory forms of bilious fever. We have occasionally employed the combination just mentioned, but have never seen any decidedly beneficial effects produced by it, while the emetic tartar, in however minute doses administered, we have found, very generally, to augment the irritability of the stomach, and increase in this manner the distress of the patient. The neutral mixture, spirits of mindererus with the sweet spirits of nitre, or a weak solution of nitre in water, we have occasionally employed, but we must frankly confess, that we are not aware of any benefit resulting in a single case from the administration of either.

Upon the propriety of blisters in bilious remittent fever, there exists not a little dispute, their use being entirely condemned by some practitioners, while others rank them among our most valuable remedies. In the more inflammatory forms of the disease, until the violence of the exacerbation has been reduced by the remedies already detailed, from the application of blisters more injury than good will unquestionably result. So soon, however, as the exacerbations have become less intense, and the remissions more marked, in all cases where considerable gastric distress remains, or any considerable affection of the head or lungs, very considerable and prompt relief will always be obtained from blisters applied over the epigastrium and right hypochondrium, to the nape of the neck, along the spine, or to the chest.

In many cases of bilious fever there is so great a degree of irritability of stomach, that not only is everything taken into it rejected as soon as it is swallowed, but the patient is tormented with almost constant vomiting, or frequent ineffectual efforts to

vomit. This distressing symptom will, very often, be completely removed by the abstraction of blood from the arm, whenever this is admissible, or by cups or leeches over the epigastrium, or by a large blister applied to the latter part. Relief will also be obtained from small portions of ice held in the mouth, from the effervescing draught, the artificial mineral water of the shops, taken perfectly cold, or from iced lemonade or toast water. Minute doses of calomel, say a third to half of a grain, suspended in some simple mucilage, and repeated at short intervals, will, very generally, promptly relieve the gastric irritability and suspend the vomiting. In cases where every other remedy has failed in relieving the irritable state of the stomach, we have repeatedly seen it promptly removed by a grain of the acetate of lead, given every hour or two, dissolved in a small quantity of water.

By a few practitioners, a mercurial course is recommended in all the more violent forms of bilious remittent fever. Calomel is directed to be given first, in large doses, as a purgative, and subsequently, in small doses, continued until its specific effects are obtained; our own experience is not, however, in favour of this practice. In the inflammatory form of the disease, a mercurial impression is calculated rather to protract than to diminish the suffering and danger of the patient, while the milder forms of the fever may be readily controlled without it. Cases, however, occasionally occur in which a strictly alterative course of mercury will be found, we are convinced, highly advantageous. We have repeatedly observed, that after the violence of the exacerbations has been reduced, the patients will continue to be affected by a low form of fever, marked by a dry skin, a small irritated pulse, a dry dark-brown tongue, frequent watery discharges from the bowels, restless nights, and a total want of appetite, and have found this condition of things to be speedily removed by a cautious mercurial course, carried even to the extent of producing a very slight tenderness of the gums. In these cases small doses of calomel, or, what is preferable, the blue mass, combined with a portion of opium and ipecacuhana, may be given every three hours until the desired effect results.

A form of the disease, somewhat similar to the one just referred to, is described by Eberle as occurring "when, either from the imprudent employment of *irritating* purges, or from other causes, the mucous membrane of the intestinal canal is brought into a state of high irritation or subacute inflammation. The disease then generally loses its remittent form, and often assumes a low typhoid character, with almost constant delirium, a tender and tympanitic state of the abdomen; a dry, dark-brown, or black crust on the tongue, with clean red edges; watery and reddish stools; great prostration; and a very dry and hot skin. Cases of this kind frequently run on for several weeks, and the convalescence is always very gradual and tedious." The treatment directed by Dr. Eberle is leeches to the abdomen, followed by a large emollient poultice; small doses of calomel and opium—one-sixth of a grain of the former to a quarter of a grain of the latter—every two or three hours. The bowels to be kept open by laxative enemata, and the patient directed to partake freely of some bland mucilaginous fluid—such as barley water, very thin oatmeal gruel, or a solution of gum acacia in water; no other article of food being allowed. "In such cases," he remarks, "I have thought that considerable benefit was derived from epispastics on the legs just above the ankles; this measure is particularly useful when the extremities are cool, while the skin of the body is hot—a circumstance which is not uncommon in instances of this kind. An emulsion of balsam copaiba may also be frequently employed with unequivocal advantage. I have so often seen the most decided benefit derived from this article, in cases attended with great irritation or subacute inflammation of the bowels, that I should consider myself neglecting an important curative means, were I to omit prescribing it in diseases of this character." "Although very considerable prostration often occurs in such cases, stimulants or tonics are by no means admissible."

Throughout the entire course of bilious remittent fever, little desire for food will be expressed by the patient, nor should any be allowed until after the disease is fully subdued; and then only barley or rice water, thin gruel or panada, in very moderate quantities. To allay the thirst, which is always present and frequently very urgent, the cold drinks, already pointed out, will be the most suitable. Perfectly cold toast water, slightly acidulated with lemon or orange juice, tamarinds, or currant or plum jelly, forms generally a very palatable beverage, of which the patient may partake at

short intervals. Small quantities of cold acidulated fluids, slowly swallowed, it is to be recollected, are far more efficacious in allaying thirst than large draughts hastily swallowed. Frequently sponging the patient's mouth with cold water, cleaning his tongue with a slice of orange, or allowing him to suck the juice of the latter, will aid very materially in abating his sense of thirst, and is always refreshing to him.

The chamber of the patient should be kept perfectly clean and cool, and, while a free ventilation is kept up, it should be guarded from any glare of light. His body should be slightly covered with bed-clothes, which, together with his linen, should be frequently changed. At all times the patient should be kept perfectly quiet, and the most perfect calmness and quietness should be maintained within and around his apartment.

In our enumeration of the symptoms of bilious fever, it was stated that great restlessness and wakefulness were very commonly present. So long as the period of increased excitement lasts, or there is any tendency to disease of the brain, the only means by which the restlessness of the patient is to be subdued and sleep procured, are the general remedies that have been already enumerated. After the morbid excitement, and whatever cerebral affection that may exist, have been reduced, a state of restlessness and an inability to sleep will often still continue from mere nervous irritability. Under such circumstances, the exhibition of an opiate in the form of Dover's powder, about bed-time, will very generally be found advantageous. By some practitioners, the extract of hyosciamus, combined with ipecacuanha, is preferred to any preparation of opium; while others, again, recommend the tincture of opium, combined with a vegetable acid, as tinct. opii ζ ss, acid. citric. gr. v. to viij, aq. puræ $\bar{\text{z}}$ ij, M.; of which a tablespoonful, or half an ounce, is a dose, to be repeated, if necessary, after a short interval.

We have now presented a general outline of the treatment of bilious remittent fever, in its mild and inflammatory forms. It is hardly necessary for us to repeat, that the extent to which each remedy is to be carried, and the propriety of its repetition and continuance, as well as the period and particular circumstances of the disease to which it is adapted, must be determined by the application of the general principles of pathology and therapeutics to each case we are called upon to treat. Although this will demand a degree of judgment in the practitioner, which he can only acquire by habits of close attention and nice discrimination, and a somewhat extended field for observation, it is the only course from which success can be anticipated in the treatment of a disease, which, like the one under consideration, varies so much in its character in different seasons and localities, and even in different individuals attacked at the same place and during the same period.

When the disease, notwithstanding our best directed efforts, runs on to that stage when its symptoms resemble those of the latter stages of typhoid fever, nothing is left us but to endeavour to sustain the patient's strength, and to remove or relieve any urgent cause of distress or danger. He should be allowed such nourishing food as is easy of digestion, as beef tea, sago, arrow-root, and the like, with wine-whey, wine, pure or diluted, porter, milk-punch, or brandy, in quantities adapted to the emergency of the symptoms and the effects produced. Sinapisms or blisters may at the same time be applied to the inside of the thighs or calves of the legs, and to the epigastrium. If diarrhoea be present, this we should attempt to abate or suspend by opiate and astringent injections. The singultus, which is often present to a very distressing degree, may be frequently allayed by the camphor julep; and the meteorism of the abdomen may often be considerably relieved by the spirits of turpentine, thirty drops of which may be given every two or three hours; this latter is said indeed to be among the safest and most useful remedies at this stage of the disease; it will often be found to produce a beneficial impression upon the diseased mucous membrane of the alimentary canal, to suspend the frequent griping stools, and to correct the morbid character of the discharges. In the sinking stage of bilious remittent fever, the effects of ammonia, with a strong decoction of serpentaria or valerian, or combined with the aromatic confection, have been represented as peculiarly beneficial; but, unfortunately, when the disease has arrived at this stage, every remedy will too often be found unavailing, and our best directed efforts to save the life of the patient ineffectual.

A question has been agitated as to the propriety of and the proper period for the

administration of quinine in remittent fever. Without attempting to detail the various and opposite opinions that have been advanced upon this subject, we shall merely remark, that in the simple and inflammatory forms of bilious remittent fever, it would be reasonably inferred from the character of the disease, that the quinine is not a remedy adapted to control the symptoms of its earlier stages, and the correctness of this inference has been very fully established by the result of experience. So soon, however, as a complete intermission has been obtained, and no indications of visceral hyperæmia or inflammation are present, a cautious administration of the quinine in solution, with the addition of a few drops of the elixir of vitriol, and to the extent of from three to five grains, repeated at such intervals as the circumstances of the case may demand, in conjunction with a cold infusion of serpentaria or some agreeable aromatic, will be found, in general, to cut short the remaining symptoms of the disease, and accelerate the period of convalescence. The more violent the form of disease has been, the more important is the administration of the quinine, so soon as a complete remission has been obtained, and the larger should be the dose of the remedy.

During the period of convalescence, the patient should be guarded from the effects of any sudden transitions of temperature, and from incurring the least degree of fatigue by sitting up too soon or for too long a period; and while his mind should be occupied and amused, at proper times of the day, by the conversation of his friends, or some light occupation, fatigue from this source must also be avoided. His bowels are to be kept regularly open, which may generally be done by allowing him to partake, in moderation, of any of the perfectly ripe subacid fruits of the season; if they, however, should become closed, some mild laxative should be occasionally administered. In regard to diet much caution is to be observed. The patient should be confined at first to moderate quantities of the more agreeable farinaceous articles; and if his strength has been greatly prostrated, a glass or two of sound wine will not be improper. As his digestive powers improve, he may be allowed plain beef or chicken broth, oysters slightly cooked, parboiled eggs, and finally, the lighter and more readily digested meats, plainly but nicely cooked. The appetite often remains, for a long time, weak and capricious—and frequently, some agreeable bitter infusion, as calombo, quassia, or the wild cherry tree bark, will be proper, to augment the tone of the stomach. In all cases, the food of the patient should be presented to him in small quantities, and served with great neatness; large masses of food, slovenly prepared and served, will in general disgust, and thus destroy what little appetite may exist. In regard to exercise and exposure to the open air, the convalescent should undertake them only so soon as he has acquired some degree of strength, when a trip to some agreeably situated watering-place will often restore him to perfect health, more quickly than can be effected during his continuance at home, where his mind is too early directed, with anxious care, to the concerns of his family, his business, or profession.

In the congestive form of bilious fever, the indications of cure are, to rouse the nervous energies of the system, to relieve as quickly as possible the central organs from their state of hyperæmia, and to restore to the capillaries of the surface their healthy action. Among the most important of the remedies calculated to effect these objects, is the external application of heat to the surface of the body in the form of the warm or hot bath, the vapour bath, or in a dry form, by bags of heated bran, salt or sand, bottles of hot water, &c. We shall often succeed in rousing the patient by immersing the whole of his body, as early as possible after he is attacked, in water, of a temperature proportioned to the urgency of his symptoms; that is, of a greater or less degree of heat, within proper limits, according as the temperature of the skin, the state of the pulse, and the general strength is more or less depressed, and the greater or less degree of torpor of the nervous system; at the same time applying brisk friction with a soft brush or a flannel cloth, to the whole surface, and particularly to the epigastrie and abdominal regions. On coming out of the bath the patient is to be rubbed dry with heated flannels, put into a well-aired bed between blankets, and supplied with some mild diaphoretic drink, as the infusion of serpentaria, of tepid warmth. A full dose of the Dover's powder, or a combination of opium, camphor and ipecacuanha, one grain each, with ten of nitre, given at this period, will often be found particularly beneficial.

Next in efficacy to the warm bath, we may rank external stimulants; sinapisms

should, therefore, be early applied to the extremities and over the epigastrium, while frictions, with some stimulating liniment, are made along the spine. By some practitioners internal stimulants have been strongly recommended, as a means of rousing the central organs from their state of torpor, and bringing on a general and moderate reaction. It is probable that in certain cases, where the stage of congestion is very considerable, and it is not promptly and permanently relieved by the remedies already recited, some mild stimulant, as ammonia, turpentine, or wine-whey, may prove advantageous, if cautiously administered and its effects carefully watched; as a general rule, however, the free use of stimulants, particularly of the more active class, is calculated to produce injury rather than good.

An active cathartic, as the combination of calomel or blue mass with aloes and extract of colocynth, followed in a few hours by the compound infusion of senna, will very generally cause a copious discharge from the bowels, of a dark-coloured, tenacious matter, and thus by assisting to unload the portal system, will often produce a marked improvement in the general symptoms of the disease. In the treatment of congestive bilious fever, the abstraction of blood from the arm, in the first period of the attack, or subsequent to the use of the warm bath and frictions to the surface, has been recommended by many practitioners as an important remedy—one indeed from which more prompt and certain relief is to be obtained than from any other that we can employ. The evidence in its favour is certainly very strong; and we believe that there are many cases in which prompt reaction may be produced, and the danger of permanent local disease prevented by its employment. The greatest judgment and caution, however, are demanded in the use of the lancet in all cases of congestive disease; the effect produced upon the pulse must be carefully watched, and the flow of blood instantly stopped if any disposition to sinking is detected. To determine beforehand the amount of blood that it will be proper to take away is impossible—the effects produced—the relief obtained, are the only guide. Even, however, when during the flow of blood the pulse becomes more free and developed, only a moderate quantity should be taken away at once—even should we have to repeat the operation after a short interval. Occasionally but a drop or two of blood will escape from the vein when it is first opened, but, after a short time, the circulation becoming more free, the blood flows in a full stream, with decided relief to the patient. It is only, however, in the early stage of the highly congestive forms of bilious fever that venesection is admissible, and even in these the flow of blood should be instantly arrested if the pulse is found to sink, or even to remain oppressed and undeveloped after a small quantity has been lost.

When prominent symptoms of hyperæmia of the brain, lungs, or other important viscera present themselves, the application of cups to the head, chest, or in the neighbourhood of the affected organ, will often be found decidedly advantageous.

As soon as reaction takes place, the use of quinia should be commenced with, in large doses, repeated at short intervals. Of the curative powers of the quinia in this form of fever we have the fullest and most unquestionable testimony. Many of the physicians of the southern and western portions of the United States place their chief reliance, in congestive remittent fever, upon the sulphate of quinia prescribed in enormous doses—twenty, thirty, and even fifty grains, repeated at short intervals until a solution of the disease is obtained; but although we are convinced of the propriety of large and frequent doses, those alluded to are certainly excessive and uncalled for.

The period of convalescence from the congestive form of bilious fever will require the same management as that from the more open and inflammatory forms.

In the highly malignant remittent, occasionally met with, in which the vital forces, crushed at once by the overwhelming intensity of the morbid cause, fail apparently to exhibit any resistance or reaction, the strength must be sustained, to use the words of Dr. Dickson, (*Essays on Pathol. and Therapeut.*, vol. i., p. 319,) by every means within our power, while we have immediate recourse to the most impressive revulsives. The hot bath, sinapisms, vesications, must be quickly and assiduously applied, while we stimulate, by the freest use of internal remedies—carefully selecting such as are best adapted to the circumstances presented. If, as is often the case, the patient suffers severely from pain in the chest or abdomen, large doses of opium or morphine must be administered, while we keep up his sinking strength by brandy, ammonia, or ether. In the superintendence of such cases we should rather incur the risk of over-

stimulating transiently, than fall below the requisite point of excitement in our use of stimulants. Dr. Dickson is fully persuaded, that he has seen more than one patient die from the timidity of his physician in this respect; who, keeping at a cautious distance behind the disease, would not venture on the exhibition of any excitant adapted to the feeble excitability, until the vital energies upon which alone stimulants can act, had become worn out and exhausted. If the stomach will bear it, it will be proper to administer, also, the quinine in full doses. The remedy will be often retained, and, whenever such is the case, will do good. "Alternate, combine, and recombine your stimulants, the effects of which may perhaps be aided by warm and nutritious fluids, wine-whey, arrow-root with wine, wine alone or spiced, brandy with milk or in mucilage. These energetic measures will usually be found effective within a very short period — improving the pulse, and arousing the general powers of the system. Yet you must not permit yourselves to be disheartened into inaction by their apparent inefficacy or slowness of impression. Persevere, not only while there is a reasonable hope, but even after all hope seems extinguished; and you will feel yourselves amply repaid by the gratification, which will not perhaps be denied you, of saving more than one fellow-creature from the destruction which seems inevitably to await him." — C.]

LECTURE XLIII.

*Epistaxis. Bronchocele; Cretinism: their Phenomena and Probable Causes
Medical and Surgical Treatment of Bronchocele.*

I YESTERDAY finished what I had to say respecting intermittent fever: its symptoms; its cause; and its cure. The subtle poison which produces it, is thickly distributed over the fairest portions of the habitable globe: blighting human health, and shortening human life, more often, and to a far greater numerical amount, than any other single cause whatever. Known only by its noxious effects, holding out no signal of its presence, this unseen and treacherous enemy of our race has yet been tracked to its haunts and lurking-places, and detected in some of its habits. It was necessary, therefore, that I should enter somewhat fully into the history of the malaria, and show how it may sometimes be shunned, sometimes be averted; how, also, in this climate at least, the effects it has already produced upon the human body may be successfully combated. But I shall not pursue, in further detail, the ravages committed by this invisible agent, and the remedies they require, in hotter and less favoured regions than our own. Of these, personally, I know nothing; and I must refer you, for information on such diseases, to authors who have seen and treated them: particularly to Drs. Lind, Jackson, Bancroft, Johnson, and Sir William Burnett.

It is customary with writers and lecturers, to pass from the consideration of ague to that of continued fever. A paroxysm of ague has been regarded as exhibiting a paradigm or sample of fever in general. But this has always appeared to me rather an ingenious refinement, than a useful matter of fact. Practically, I see nothing to be gained by the association. Intermittent fever, it is true, does often run, in hot climates, into the remittent, and the remittent into the continued form. But these are very different disorders from the continued fevers with which, in these climates, and in this country, we have to do. Intermittent fever, and continued fever, as we see them, differ in their phenomena, in their cause, and in their treatment. They are alike, inasmuch as they both are called fever, and both are attended, in some part or other of their course, with *pyrexia*; but in essential symptoms, I have known many a compound fracture more like continued fever than any ague that we are likely to witness. I shall take up the subject of continued fever, then, in connexion with the eruptive febrile diseases, with which it has many strong links of analogy; and I

resume the consideration of the disorders that come within the province of the physician, according to their anatomical seat.

After what was stated of hæmorrhage in general, in an earlier part of the course, I hardly know whether *epistaxis* needs or deserves any formal notice. There are, however, some points relating to this simple, and commonly harmless hæmorrhage, which it may be worth while very briefly to touch upon. Sometimes it is a remedy; sometimes a warning; sometimes really in itself a disease. The readiness with which the mucous lining of the nasal passages pours forth blood is familiar to the experience of every school-boy: who "often wipes a bloody nose." A slight blow, brisk exercise, a strong bodily effort, a fit of sneezing, or the summer heat, is sufficient, in many boys, to make the nose bleed; and this facility of hæmorrhage furnishes, often, an index of some unnatural state of the circulation: and especially of undue fullness of the vessels of the head. But the import of this symptom is not always the same. Epistaxis may indeed be taken as affording an epitome of the various forms of capillary hæmorrhage. In childhood and early youth it is idiopathic, dependent upon active congestion, and probably arterial. It is nature's favourite mode of blood-letting at that period of life. In old age it is symptomatic, the result of passive or mechanical congestion, and probably venous. In some adult persons it happens periodically, and is habitual: and its *suspension*, rather than its *occurrence*, becomes a token of disease or of danger. In young women it is not seldom vicarious of suspended menstruation: in men it is apt to take the place of hæmorrhoids. Lastly, it may proceed from disease in the nares themselves; or form a part of a more general hæmorrhagic disorder.

It is unnecessary to go at length into the phenomena of epistaxis. The main phenomenon becomes obvious at once both to the patient and to those around him: and the accessory and incidental circumstances are easily discoverable when the attention is aroused to them by the sight of the blood. Usually the blood flows *guttatim*; in a succession of drops; but these may follow each other so fast as to constitute a little stream. Sometimes a few drops only fall; sometimes several pints are lost. A moderate hæmorrhage of this kind is generally succeeded by a sense of relief and refreshment. A large efflux of blood may cause pallor, faintness, debility, exhaustion, even death.

Active idiopathic epistaxis, as it occurs in children, is almost always salutary, and may be left to work its own cure. When it runs into excess, or is too often repeated, it may be checked by applying cold water to the forehead and to the bridge of the nose. The sudden contact of some cold substance with a distant part of the surface of the body will often have the effect of restraining the hæmorrhage: apparently by producing a general and sympathetic constriction of the superficial blood-vessels. This is doubtless a reflex phenomenon. The nursery remedy is to slip a cold key down the child's neck, between its back and its clothes. The aspersion of cold water is still better. The matico leaf, crumbled into a powder, and snuffed up the nostrils, will often stop the bleeding at once. Besides these external appliances, cooling laxatives should be given; and if the bleeding prove obstinate, some astringent internal remedy may be thought proper. Those which I have hitherto found the most efficacious are the gallic acid and the acetate of lead. But I have been recently informed by Dr. Latham that his experience has led him to trust much to *mercury* in the management of epistaxis; and that the same indications have governed him, in adapting its use to this form of hæmorrhage, as serve to guide him in cases of inflammation. Thus, when the hæmorrhage has been profuse and frequent, and moderate depletion by blood-letting, or by purgatives, has not arrested it, he has brought the constitution rapidly under the influence of mercury, and as soon as the mouth became sore, the hæmorrhage has ceased, not a drop more of blood has been lost. Again, when the epistaxis has been, not copious, but habitual or frequently recurring, without any excess of vascular action, or any other apparent ailment in the constitution at large, Dr. Latham has often cured his patient by a moderate salivation, gradually induced, and continued for a few weeks.

In conversing with Dr. Southey on the same subject, I find that he also has been taught by experience to rely upon mercury as almost a specific remedy for obstinate

hæmorrhage, occurring under similar conditions, from whatever organ of the body it may proceed.

This plan of treatment it is therefore my purpose to prove, as future opportunity may permit.

[Habitual epistaxis may often be suspended without danger to any internal organ by a blister to the back of the neck. — C.]

When epistaxis *begins* to show itself in advanced life, it is a symptom which cannot safely be neglected: for it indicates that the veins of the head are loaded. It implies a morbid condition that requires to be redressed. You will look for disease of the heart—or for threatenings of apoplexy—and take your measures accordingly. The blood-vessels which ramify upon and beneath the pituitary membrane, communicate by indirect inosculation with the veins and sinuses of the skull, as well as with the jugular veins. You see, therefore, how it is that hæmorrhage from this membrane may perform the office of a safety-valve, and protect the important organ within the cranium from impending mischief.

On the other hand, when epistaxis, which is known to have been habitual, fails to recur at or about the usual periods, you will look, with a jealous care, into your patient's state, and watch for and obviate any tendency to plethora capitis.

When epistaxis forms a part of more general hæmorrhagic disease—as when it occurs among other symptoms of purpura—its treatment merges in that of the whole malady.

In any case, if the flow of blood be excessive, and cannot be restrained by the ordinary remedies, but is exhausting the patient's strength, it becomes an absolute disease and it will be requisite to staunch the blood by manual expedients.

These consist in stopping the bleeding orifices mechanically; which is most effectually to be done by plugging the cavity. A dossil of lint must be carefully inserted into the bleeding nostril. Its mechanical effect, which is pressure, may be chemically aided by first wetting the lint with a saturated solution of alum. The mode of introducing these plugs it is the business of the surgeon—and not mine—to teach. The operation is not a very comfortable one either to bear or to perform.

A very simple mechanical remedy has been lately announced by Dr. Negrier, of Angiers; who discovered it (he says) by mere accident. The patient is to raise one or both of his arms above his head, and to hold them for some little time in that position. Dr. Negrier declares that, during an experience of three years, he has never known this method fail to arrest the bleeding. His explanation of its *modus operandi* is not very satisfactory. The expedient itself is however so easy, so prompt, and, even if unsuccessful, so harmless, that its real value deserves to be tested—and will soon probably be settled—by an ampler trial.

[In broken-down constitutions—especially in persons of long-continued intemperate habits—a form of epistaxis will often occur, which it is very difficult to control. Besides mechanically plugging up the nostrils in these cases, we have found the most effectual remedy to be quinine, given in conjunction with either the gallic or tannic acids, and a moderate portion of opium.—C.]

Before we trace this mucous membrane downwards, through the mouth, to the inside of the throat, let me turn your attention to a singular disorder which may be deemed external, for it is scarcely more than skin deep: I mean that enlarged state of the thyreoid gland to which the name of *bronchocele* has been given. This word is not merely derived from the Greek, but was used by the Greek writers in the same sense in which we now employ it. In Switzerland, where it is very common, and in France, the complaint is called *goître*; a corruption, it is believed, of the Latin “guttur,” the throat. It is known in England as the *Derbyshire neck*; from its frequent occurrence in that country.

The term bronchocele has been sometimes applied indiscriminately to all protuberances or swellings in front of the throat; or, at any rate, to all enlargements of the thyreoid gland; whereas it should be restricted to *hypertrophy* of that part: an exaggeration of its natural structure, with augmentation of its volume. The texture of

the gland becomes coarser; its blood-vessels grow larger and more numerous; its cells are magnified, and filled with a thick, viscid secretion. It usually presents a soft, smooth, elastic tumour, which is neither painful, nor tender, nor discoloured. The lobes of the gland become more obvious. Sometimes the whole tumour is irregularly lobulated: sometimes the exact form and relative proportions of the gland are preserved, each lobe and portion being equally increased in size. Occasionally there is a soft uniform or irregular swelling, without much distinction of parts. Alibert states that the right lobe is more frequently enlarged than the left. Mr. Rickwood found it so in every instance of bronchocele that came under his notice in the neighbourhood of Horsham.

Unless the tumour be very large, it follows all the motions of the larynx: and this is a point of considerable importance whenever the diagnosis is at all doubtful. It is just possible that an enlarged lymphatic gland, or an encysted tumour in the neighbourhood of the larynx, or even a collection of pus thereabouts, might, in some degree, embarrass the diagnosis. But, by placing the head and neck in different successive positions, swellings of this accidental kind may, in general, be ascertained to be unconnected with the larynx: and they do not follow its up and down movements when the act of deglutition is performed.

It is of importance to know, also, that the gland itself is subject to different kinds of enlargement. It may swell from inflammation, chronic or acute: and then it will be hard, and tender, and painful. But it does not seem very prone to inflame; and probably Dr. Copland is right in his opinion that inflammation occurs spontaneously in this organ in scrofulous persons only. Baillic and Alibert speak of it as being occasionally the seat of cancer; but that must be very rare. Sometimes cartilaginous

FIG. 29.

Goitre. From a preparation in Professor Mütter's collection.

or ossific deposits take place in the gland. It is necessary, I say, to be aware of these circumstances, and to distinguish one kind of thyreoid tumour from another: for some of the morbid changes just referred to are clearly beyond the power of any *medicine* to remove; and if all forms of enlargement incidental to this part are lumped together under one common name of bronchocele, we shall be liable to arrive at false conclusions concerning the power of remedies over that disease.

Bronchocele is not, *in itself*, a painful disorder: nor does it taint the system, or affect the constitution in any way. It has no quality of malignancy about it. It is always, however, a deformity; and by its mechanical effects, that is, by its weight when large, and by the pressure it exercises on contiguous parts, it may occasion great distress, and suffering, and even death itself. The size, and the effects, of the

tumour both vary much in different cases; but its *injurious* effects are not always, though they are generally, in proportion to its bulk. Sometimes there is no more than a slight fullness of the throat, which some persons, I believe, think rather graceful than otherwise. Now and then, the swelling, after its first commencement, develops itself with great rapidity; but its ordinary progress is slow. It often continues for months, or years, without reaching any extreme or very troublesome magnitude. Sometimes it remains stationary for a considerable time, and then *suddenly* increases, without any apparent cause. The worst effects of bronchocele are its interference with the circulation, and with respiration. By its pressure it may obstruct the free descent of the blood through the veins of the neck, and give rise to headache, giddiness, noises in the ears, confusion of thought, and a turgid condition of the head and face. Or, by pressing upon the wind-pipe, it may cause hoarseness, wheezing, and dyspnoea. It may even impede deglutition. But these effects, I say, do not depend altogether upon the actual size of the tumour. A very large goitre may produce no other inconvenience than what results from its weight, and its unseemly appearance. It may surround all the front and sides of the neck like a thick collar, and rise as high as the ears; or it may hang down in a pendulous lump,

FIG. 32.

Bronchocele, from the King's College collection. The oesophagus is seen to be pushed to the right side by the tumor.

and be supported upon the chest. Nay, the tumour is said to descend, in some rare instances, so low as to be in contact with the abdomen: and Alibert mentions one case in which the swelling was of a tapering cylindrical shape, and reached to the middle of the thigh. On the other hand, a small tumour, not bigger than one's fist, especially if it happen to occupy the central portion, or what is called the isthmus, of the gland, may so press inwards upon the trachea as materially to hinder the breathing, and even to threaten suffocation. A pupil now attending the hospital has informed me of a case, which he himself saw, of death produced by the encroachment of a bronchocele; not so much, however, from suffocation as from starvation: for the swelling encircled the trachea, and came at last to press so much upon the woman's oesophagus, that she could not get food into her stomach. I suppose that the reason of these differences may be sometimes found in the manner in which the tumour grows, and in its relative situations. When it is bound down by the muscles of the neck, it presses, as it continues to enlarge, upon the parts behind it. When it is not so confined, the skin readily yields, and the entire growth of the tumour takes place anteriorly.

This disease is much more common in women than in men. Indeed we seldom see it, in this country, except in females. Yet I happen to have an example of it now (December, 1837) in a male among my patients in the hospital. Dr. Andrew Crawford states that forty-nine cases were admitted into the Hampshire County Hospital, in ten years, and forty-eight of these were in women. Of seventy patients admitted at the Chichester Infirmary in nine years, two only were males, and they were boys of a very feeble and feminine habit, and backward for their years. Among one hundred and sixteen patients of Dr. Manson's fifteen were men. Taking an average from these three lists, we have one male for twelve females. It is well to bear in mind that our fashion of dress renders a small bronchocele much more noticeable, much less easily concealed, in women than in men. In the former the swelling has been known to come on, or at any rate to increase rapidly, during their confinement in child-bed: and it is frequently observed to undergo a temporary enlargement at the menstrual period. Dr. Copland has seldom met with an instance in the female, unconnected with some kind of irregularity in the catamenial discharge, or disorder of the uterine functions; and he never saw a case in which the disease made its appearance before the period of commencing puberty. In Switzerland, and in some parts of India, where the complaint is much more prevalent than here, the proportion

of males affected is greater; and it begins, often, prior to the age of puberty, in both sexes. It seldom shows itself earlier than the age of eight or ten. Dr. Elliotson states, indeed, that he himself, when in Switzerland, saw goitre in a little boy only four years old; and the natives told him that it rarely made its appearance before the age of six. But children have been *born* goitrous. M. Godelle, physician to the hospital at Soissons, had a preparation of the body of an infant, which lived a few hours only, and which came into the world with a goitre; the mother being affected with the same disease. A case is mentioned in the *London Medical Repository* of a child born in Derbyshire with bronchocele of considerable size. The disease, therefore, undoubtedly may be *congenital*: and one of the facts I have just mentioned points to the question of its being *hereditary*. It is said to be so; and there is much probability in favour of that opinion. Children born of goitrous parents often have goitre. But that, you will say, may depend upon their being in the same place, and exposed to the same causes, which produced bronchocele in the mother or father. Dr. Crawford states, however, that he knew a woman, with goitre, whose grandmother, father, paternal aunt, and cousins, also had it, although they did *not* all live in the same place, and no other person in their respective neighbourhoods was affected by the disease.

Admitting, what seems probable, that the disease may sometimes be hereditary, in the sense in which I formerly explained that term, there can be no doubt that it is often *acquired*.

In the first place bronchocele is *endemic*—prevalent in certain localities, and scarcely occurring elsewhere. And persons who, being previously well, go to live in those localities, often become affected with the complaint: and persons who migrate *from* those localities, having the complaint upon them, sometimes get rid of it by the mere change of residence. The physical circumstances of the places thus selected by the disease have been studied with the natural hope of discovering what the cause may be of an effect so singular. Some morbid quality of the *air* was long suspected. The habitats of the unknown cause of bronchocele appeared at first sight to be very much like those of the malaria. Goitre abounds in the hollows of many mountainous districts; among the Alps, for example, and in the Pyrenees. This was notorious to the ancients. Juvenal asks—

Quis tumidum guttur miratur in Alpibus?

And it is in the deep, close, and humid valleys of Switzerland, which lie at the feet of, and between, high mountains, that bronchocele is most common. Several writers, who have personally investigated this subject in places where goitre is rife, concur in the belief that it depends upon insalubrity of the air, arising from the peculiarities of the situation. They affirm that it is most frequent in low, damp, confined spots, where the stagnant atmosphere is seldom stirred by wholesome breezes; and where the sun, in summer, has great power. Dr. James Johnson remarks, "We find in the Valais (one of the Swiss cantons) and in the lower gorges or ravines that open on its sides, both cretinism and bronchocele in the most intense degrees. As we ascend the neighbouring mountains, cretinism disappears, and goitre only is observed. And when we get to a certain altitude, both maladies vanish." Dr. Reeve, again, states that "all the cretins he saw were in adjoining houses in the little village called La Batia, situated in a narrow corner of the valley, the houses being built up under ledges of the rocks, and all of them very filthy, very close, very hot and miserable habitations. In villages situated higher up the mountains, no cretins are to be seen."

The *cretinism* mentioned in these quotations is a strange and melancholy disease: a sort of idiotey, accompanied by (and doubtless dependent upon) deformity and imperfection of the bodily organs. The mental affection exists in all degrees, from mere obtuseness of thought and purpose, to the complete obliteration of intelligence. Many of the cretins are incapable of articulate speech; some are blind, some deaf, and others labour under all these privations. They are mostly dwarfish in stature, with large heads, wide vacant features, and goggle eyes, short crooked limbs, flabby muscles, and tumid bellies. The worst of them are insensible to the decencies of nature, and obey, without shame or self-restraint, every animal impulse. In no other class of mortals is the impress of humanity so pitifully defaced.

More recent and extensive observation of the localities infested by goitre have rendered it improbable that the disease derives its origin from any deleterious properties of the air. Certainly it is not owing to anything that is common to *all* mountainous countries. Some parts of Switzerland are free from it. So are the Highlands of Scotland. It is met with also in flat situations—as in Norfolk. I have seen several cases of it in Cambridgeshire, which is a *very* flat county. In one village in particular, about five miles from Cambridge, it is extremely common. There are some striking facts collected by the celebrated and philosophic Humboldt, which go to show that the prevalence of bronchocele does not depend on any particular configuration of the surface of the earth, nor on any peculiar condition of the atmosphere. He tells us that in South America bronchocele is met with, both in the upper and the lower course of the Magdalen river; and in the flat high country of Bogota, 6000 feet above the bed of the stream. The first of these regions is a thick forest; while the second and third present a soil destitute of vegetation. The first and third are exceedingly damp; the second peculiarly dry. In the first the air is stagnant; in the second and third the winds are impetuous. In the first two the thermometer keeps up all the year at 22 or 23 degrees of the Centigrade scale: in the third it ranges between 4 degrees and 17.

The researches of Mr. McClelland, in India, lead to the same conclusion. He found goitre extremely frequent in one portion of the district which he surveyed, while the other portion was almost exempt from the complaint, “although an equality of moral as well as physical circumstances appeared to affect the whole. The external alpine characters of the province are the same in every part, the inhabitants all belong to the same tribes of Hindoos, and are subject to fewer irregularities in their mode of life than any other people in the world.”

The different localities of the villages, in the portion where goitre was *not* prevalent, he describes as being as diverse as can well be imagined. “Some are erected on narrow ridges, others in deep valleys, surrounded by abrupt and lofty mountains; others on rugged declivities, between lofty peaks on one side, and deep ravines on the other, into some of which the sun can scarcely penetrate. The different altitudes of these villages vary from 2000 to 6000 feet.”

Facts of this kind have turned the attention of scientific inquirers towards the only other obvious source to which the disorder could, with probability, be attributed, viz., the quality of the *water* used for drinking. Wherever goitre prevails, the popular belief assigns it to the water, as a cause: and the more accurately the search is prosecuted the more strength and likelihood does this supposition acquire. Its very universality is a presumption in its favour. The disease was formerly ascribed to the use of *snow* water: a notion which originated, I imagine, in its frequent occurrence in alpine regions. But the people in almost *all* the valleys of Switzerland drink the water that comes from the Glaciers; while bronchocele is known in *some* of the valleys only. It prevails also in certain spots where pump water is used, and *there* the people accuse the *pump* water of producing it. Besides, goitre occurs in other countries, where the snow never lies long, as in Derbyshire; and even in Sumatra, where there is *no* snow. Dr. Bally, a native of a goitrous district in Switzerland, believes that bronchocele is caused by certain *waters*, which issue from the hollows of rocks, trickle along crevices of the mountains, or rise from the bowels of the earth. And in support of that opinion he refers to some fountains in his own neighbourhood, the drinking of the water of which will produce, or augment, goitrous swellings, in eight or ten days. Such of the inhabitants as avoid these waters are free, he says, from goitre and cretinism. In Captain Franklin’s narrative of his expedition to the shores of the Polar sea, there is the following statement, made by his fellow traveller, Dr. Richardson:—“Bronchocele or goitre is a common disorder at Edmonton. I examined several of the inhabitants afflicted with it, and endeavored to obtain every information on the subject from the most authentic sources. The following facts may be depended upon:—The disorder attacks those only who drink from the *water* of the (Saskatchewan) river. It is indeed, in its worst state, confined almost entirely to the half-bred women and children who reside constantly at the fort, and make use of river water, drawn, in winter, through a hole made in the ice. The men, from being often from home on their journeys through the plain, where their drink is *melted snow*, are less affected: and if any of them exhibit during the winter some incipient symptoms

of the complaint, the annual summer voyage to the sea-coast generally effects a cure. The natives, who confine themselves to *snow water* in the winter, and drink of the small rivulets which flow through the plains in the summer, are exempt from attacks of this disease. A residence of a single year at Edmonton is sufficient to render a family bronchocelous. Many of the goitres acquire great size. Burnt sponge has been tried, and found to remove the disease: but an exposure to the same cause immediately reproduces it. A great portion of the children of the women who have goitres are born idiots, with large heads, and the other distinguishing marks of cretins. I could not learn whether it was necessary that both parents should have goitres to produce cretin children."

We are able even to go a step further, and to announce a probable conjecture as to the specific quality of the suspected water. Bronchocele is very prevalent in Nottingham and its neighbourhood; and the vulgar there ascribe it (so Dr. Manson informs us) to the *hardness* of the water. You know that the rough practical distinction between soft and hard water is that the former *dissolves* soap, while the latter *decomposes* it. The hardness is generally occasioned by the presence either of *sulphate of lime*, or of *carbonate of lime*. In the one case the remedy is to mix the carbonate of an alkali with the water; in the other you simply boil it. Now the well water in and about Nottingham is more or less hard, and unfit for the purpose of washing. Dr. Coindet, of Geneva, declares that the use of hard or pump water in the lower streets of that town brings on the goitre very speedily. At Cluses, on the Arve, numerous cretins and goitrous persons are seen in the streets: lofty cliffs of limestone tower over the town, and through its caverns copious streams of water find a passage. The soil in the neighbourhood of Edmonton was found by Dr. Richardson to be calcareous, and to contain numerous fragments of magnesian limestone. In a *Treatise on English Bronchocele*, very recently published, Dr. Inglis states his belief that the presence of magnesian limestone always implies the co-existence of the disease. "Take (he says) that ridge of magnesian limestone running from north to south through the centre of Yorkshire, and marging the shires of Derby and Nottingham. All along that line we have goitre to a very great extent; whereas, on our diverging to either side, the disease is found to diminish."

These scattered indications that the hurtful quality of the water is somehow derived from its contact with limestone rocks, receive a powerful corroboration from the result of Mr. McClelland's minute and valuable inquiries, which were carried on in the province of Kemaon, south of the Himalayan mountains. I have not been able to obtain his book; what I am about to tell you I take from a full and instructive notice of it in the fifteenth number of the *British and Foreign Medical Review*. Mr. McClelland finding goitre very abundant (as I mentioned before) in one great section of a district, and almost entirely absent from another section, set himself to find out in what other particulars these sections were distinguished from each other. He ascertained that they completely agreed "in external aspect, altitude, and climatology," but differed remarkably "in their geognostic relations; and this distinction was even traced down to the very villages in which the disease is found, with such perfect nicety, as to enable one almost to predict *à priori*, on examining the rocks of a neighbourhood, whether the inhabitants are affected with goitre or not."

It would be impossible for me to give you even an abstract of Mr. McClelland's numerous observations; but I select one or two striking instances in favour of his opinion that the endemic prevalence of goitre is connected with the use of water impregnated with calcareous salts.

One extremity of the long village Deota, which occupies half a mile of the foot of Durge mountain, is inhabited by Brahmins; the other by Rajpoots and Domes. Of the first caste there are about twenty persons, all of whom are free from goitre. There are forty of the second, and two-thirds are affected, more or less. Of the third caste, forty-six in number, nearly the whole are goitrous. "To what cause can we ascribe the immunity of one caste of the inhabitants of this village, and the almost universal affection of the other two castes? They are all alike well-fed, and have little toil: their land producing the requisites of life almost without labour. Difference of caste does not here imply a difference of pecuniary circumstances, and consequently of the comforts of life. In these respects the three castes in this village are on perfect equality. Nor will hereditary predisposition acquired by intermarriages be sufficient

to explain the interesting fact: for the affected parties are confined to the Rajpoots and Domes, who cannot intermarry, while the Brahmins and Rajpoots may. The village is raised about one hundred feet above the level of the valley; and the mountain, at the foot of which it is situated, rises with a gentle slope, and is not in this vicinity at all rugged. It is chiefly composed of transition limestone, and the village is erected on a conglomerated rock, composed of calcareous tuff, inclosing fragments of other rocks. There is a spring in the valley, about one hundred yards from the village, bearing on its first appearance the character of a mineral spring. The water bursts forth with strong ebullition, in the quantity of at least forty gallons in a minute, and agglutinates the sand and gravel by which it is surrounded, by the deposition of calcareous tuff. The temperature and quantity of the water is the same at all seasons. The former inhabitants of the village, aware perhaps of the noxious effects of this spring, had an aqueduct formed, by which water is conveyed into the Brahmin portion of the village from a distant source. The aqueduct having been suffered to get out of repair, the quantity of water it transmits is reserved exclusively for the Brahmins; except during the rainy season, when, the water being plentiful, the Rajpoots also use that of the aqueduct; but the Domes have no alternative at any season but to use the water from the spring."

The valley of Baribice is elevated 4000 feet above the sea. Its eastern extremity is composed of *clayslate*, and in five villages, containing 152 inhabitants, there is not one goitre. The other extremity of the valley is partly composed of limestone; and of 192 inhabitants, distributed in six villages, 70 are affected with goitre: but Duey-gong, one of these villages, supplied with water from clayslate, has not a single case of the disease; while Agar, only half a mile distant, and containing 50 inhabitants, has no less than 40 cases; and of that number 20 are cretins. They use the water which issues from an old copper mine in limestone, and which contains carbonate of lime, and of soda, but no sulphate.

Mr. M'Clelland affirms that in the course of his personal inquiries, which extended over 1000 square miles, and which were prosecuted without regard to any theory, no instance occurred in which goitre prevailed to any extent where the villages were not situated on, or close to, limestone rocks.

[In the United States the disease is prevalent in many of the valleys situated in the mountainous regions of New Hampshire, Vermont, New York, Pennsylvania and Virginia; many of these regions abound in limestone rocks. — C.]

Cretinism has a close, but an ill-understood, connexion with goitre. Wherever cretinism is endemic, bronchocele never fails to be abundant. But bronchocele may prevail in a place where there are no cretins. With but few exceptions, cretins are goitrous; whereas many of those who have bronchocele are not affected with cretinism. The two disorders either spring from the same cause, requiring for their joint production that this cause should be in active operation; or, if they have separate causes, these frequently co-exist and act in combination. It is said, I know not with what accuracy, that when both parents are goitrous for two generations in succession, the offspring, being in the third generation, are sure to be cretins. Certainly cretinism is most common where bronchocele is most common, and especially in mountainous places. It occurs in the Pyrenees as well as in the Alps, in the mountains of Syria, in the hilly parts of China, and in the Himalayan regions. Yet cretinism is confined within much more limited bounds than goitre. Saussure, Foderé, and Dr. Reeve, agree entirely as to the circumstances under which cretinism appears to be most commonly engendered in Switzerland. They say that the disease is usually met with in the valleys which are nearly surrounded by high and steep rocks, where there is but little circulation of air, and where the inhabitants are exposed to the direct rays of the sun, and to the reflexion of them from the rocks: and also to effluvia from marshes. It is in the filthy habitations built in these close, hot, and humid situations, that cretinism abounds most. The children that are taken away from the low valleys, and carried up, when young, into the high grounds, escape the disease; or even get the better of it if removed soon enough. And the amendment is said to be perceptible even in a very few days. These facts have led many persons to conclude that cretinism, if not bronchocele, depends on some condition of the *air*. It

appears to me probable that the exciting cause of both is the same, and that the local circumstances just now mentioned operate as predisposing causes only. Cretinism, as well as goitre, was observed, by Ramond, in the "open, well-watered, and well-ventilated valleys of the Pyrenees."

There are some difficulties opposed to the implicit reception of the opinions formed by Mr. McClelland and by others, respecting the origin of these diseases. And the facts upon which those opinions are grounded are not without apparent exceptions. Moreover, the actual substance which exercises or confers the noxious power, has yet to be ascertained. This etiological problem, so full of interest, is not solved. One step more, and probably one step only, remains to be taken. We look to the medical geologist for its complete solution; and I trust that, now, we have not long to look. The deleterious agent has been traced, with tolerable certainty, to water: and hence to some element of the soil washed by that water. And if what at present is probable only, shall hereafter be proved, — namely, that the hidden cause of goitre and of cretinism lurks in some chemical quality of man's natural beverage — it can scarcely be doubted that chemistry will be found ready to supply a simple and effectual corrective of the evil. This hope it is which makes it so important that medical men should be accurately possessed of the present state and bearings of the question; and prepared to take advantage of every opportunity that may arise for its practical determination. For surely it would be a noble achievement of our art, and a signal blessing provided for hundreds of human beings yet unborn, thus to prevent the deformity, the discomfort, and the sometimes danger, of bronchocele; and to forbid, in its very source and fountain, the more hideous and loathsome disfigurement, of mind as well as of body, that distinguishes the wretched cretin.

I ought, perhaps, to tell you, that other causes, many of them very vague and unsatisfactory, have, at different times, been assigned. Thus Valentin supposes the disease to be more common in women than in men, simply because women more frequently have the neck uncovered. It has been affirmed that young females who have taken the veil in catholic countries have lost their goitres in consequence of the change then made in their costume; and a medical man in Guatemala asserts that the same infirmity has sensibly diminished among the men in that part of the world, since cravats became fashionable there. These views of the matter accord with some whimsical notions entertained by the late Sir Anthony Carlisle. He held that the chief purpose of the thyreoid gland was to protect the delicate organ of the voice from the injurious influence of cold; and he consequently regarded the tumour of bronchocele as being rather of a sanative than of a morbid nature. He looked upon it as an additional greatcoat thrown over the important instrument of speech, in circumstances of extraordinary need. His theory agrees with some of the facts on which other theories, not perhaps more plausible, have been founded. Thus although snow water may not be, indeed I may say certainly is not, the cause of bronchocele from any peculiar quality that belongs to it, yet the disorder is confessedly frequent in many places where snow water is habitually drunk; *i. e.*, as Sir Anthony would have reasoned, where *very cold* water is frequently drunk; the swelling being a provision of nature to obviate the hurtful effects which might else be produced on the larynx by these cold potations. The summer change for the better, described by Dr. Richardson, consists also with the same theory: which would suggest the covering an incipient bronchocele continually with warm clothing, such as flannel, to check its growth, to obviate its necessity, and so gradually to occasion its subsidence. And this plan is mentioned, I see, by Bouillaud, among the curative indications.

I mention these theories, not because I have any faith in them myself, but as being curious specimens of the manner in which the human mind strives to account for obscure phenomena; and as showing how readily facts may be culled and pressed into the service of very slender and infirm hypotheses.

One very important point — preliminary to all rational *treatment* of bronchocele or of cretinism — is obvious; the removal of the sufferer, whenever that can be done, from the infested locality. This was the first care of that great friend of the unhappy race of cretins, the benevolent Dr. Guggenbühl, who has founded on the Abendberg in the Bernese Alps, at an altitude considerably higher than that below which these kindred disorders are generally met with, a hospital for the reception of cretin children. To their cause and comfort Dr. Guggenbühl has generously devoted his whole mind

The success of this philanthropic experiment, the beneficial influence of pure air, and of judicious medical and moral discipline upon these poor patients, has been signal and gratifying. Of the whole number of cretins admitted during a period of twelve years, one third were perfectly restored to health and reason, while the rest improved much both in body and in mind.

This most useful and praiseworthy institution has proved the parent and model of the Asylums for Idiots which now exist, and are happily multiplying, in England and elsewhere.

When removal to a more salubrious place has been accomplished, or when the disorder occurs sporadically, as it sometimes does, we may administer drugs with better hope and advantage. Now a great variety of empirical remedies have been recommended for the cure of bronchocele, concerning most of which it would be a waste of time for me to speak at all. The remedy which, as an internal medicine, has of late years superseded all others, and acquired the reputation of a specific against goitre, is iodine: and it certainly has a remarkable influence over the genuine unmixed form of the disease, whether endemic or sporadic—the hypertrophied gland; yet it does not, perhaps, merit the title of specific in the same absolute sense as that in which we say that bark is a specific for the ague, or sulphur for the itch. Dr. Coindet, of Geneva, was the first who made this remedy extensively known. Dr. Straub, however, of Hofwyl, has laid claim to the priority of its use. Probably that happened in this matter, which has often happened in others, viz., that the state of knowledge was ripe for such a discovery, and it was made by each of these physicians independently of the other. Dr. Coindet's name, however, has been inseparably connected with the application of iodine to the cure of bronchocele, in a work which, if he had no other claim to be remembered, would immortalize his memory;—I mean Sir J. Herschel's profound and beautiful *Discourse on the Study of Natural Philosophy*;—a book which I should advise those among you who have not already read it, to make themselves masters of as soon as they have leisure to do so. He thus strikingly illustrates an observation of his own, that mighty benefits often accrue to science from the casual experience of even unscientific or illiterate persons. “A soap manufacturer remarks that the residuum of his ley, when exhausted of the alkali for which he employs it, produces a corrosion of the copper boiler, for which he cannot account. He puts it into the hands of a scientific chemist for analysis: and the result is the discovery of one of the most singular and important chemical elements—iodine. The properties of this being studied, are found to occur most appositely in illustration and support of a variety of new, curious, and instructive views then gaining ground in chemistry; and thus exercise a marked influence over the whole body of that science. Curiosity is excited; the origin of the new substance is traced to the sea-plants from whose ashes the principal ingredient of soap is obtained; and ultimately to the sea-water itself. It is thence hunted through nature, discovered in salt-mines and springs, and pursued into all bodies which have a marine origin: among the rest into sponge. A medical practitioner, Dr. Coindet, of Geneva, then calls to mind a reputed remedy for the cure of one of the most grievous and unsightly disorders to which the human species is subject—the goitre—which infests the inhabitants of mountainous districts to an extent that, in this favoured land, we have happily no experience of, and which was said to have been originally cured by the ashes of burnt sponge. Led by this indication, he tries the effect of iodine on that complaint, and the result establishes the extraordinary fact that this singular substance, taken as a medicine, acts with the utmost promptitude and energy on goitre, dissipating the largest and most inveterate in a short time, and acting (of course, like all medicines, even the most approved, with occasional failures) as a specific, or natural antagonist, against that odious deformity.”

It is curious enough, and marks the accuracy with which the effects of remedies may be observed, that not only had burnt sponge been found efficacious in removing bronchocele, but the bladderwrack also, the fucus vesiculosus, the plant that, with others of the same family, yields the soda wherewith the iodine was found combined. Dr. Gairdner, who was the first I believe in this country to write on the effects of iodine, accounts for the frequent failure of even large doses of the burnt sponge, by showing that it was much adulterated with charcoal. Dr. Manson, of Nottingham, has published the following tabular statement of the results of the employment of

iodine by himself. He had treated one hundred and sixteen patients, of whom fifteen were men, and the rest women. Of the fifteen men, ten were cured, three were improving and under treatment at the time of his publication, one was dismissed for irregular attendance, and one was much relieved. Of the one hundred and one women, sixty-six were cured, nine much relieved, two received no benefit, ten were discharged for irregular attendance, and fourteen were improving under treatment. Of the whole one hundred and sixteen, therefore, there were seventy-six positive cures, or two-thirds of the entire number; and only two positive failures. Dr. Coindet was successful in about the same proportion of cases. This is strong evidence of the power of the remedy. Dr. Manson found that in some, but not in all individuals, after the preparations of iodine had been given internally for a certain time, they were apt to occasion headache, giddiness, sickness of stomach, with some degree of languor, and inaptitude for exertion. His plan in such cases was to suspend the use of the medicine, or to reduce the dose. The following effects of the iodine are stated by Dr. Coindet as having occurred in his practice:—Acceleration of the pulse, palpitation, dry cough, watchfulness, marasmus, and prostration of strength. Sometimes swelling of the legs supervened, tremors, painful hardness of the bronchocele, diminution of the breasts, or a remarkable increase of appetite; and he adds that in almost all the instances which he had observed, a very rapid diminution, or a disappearance more or less complete, took place, during these symptoms, of even hard, bulky, and old bronchoceles. His doses varied from somewhat less than a grain to somewhat more than a grain and a half. This was certainly, as Dr. Manson has suggested, too large a quantity of this powerful drug for the generality of patients. The management of the remedy is now better understood. I have never seen any of the unpleasant consequences enumerated by Dr. Coindet. These practitioners gave the iodine in the form of a tincture. But that is a bad mode of exhibiting it: for the tincture is decomposed in any aqueous menstruum, and the iodine thrown down to the bottom. Under such circumstances the patient may at one time get no iodine at all, and at another time a dangerous dose: for you are aware that iodine is an active irritant poison. But if you mix iodine with iodide of potassium, it is then *held* in solution: and this is the form in which it is now commonly given. In the last edition of the Pharmacopœia there is a *Liquor Potassii Iodidi compositus*, made by dissolving five grains of iodine, and ten of the iodide of potassium, in a pint of distilled water. This will doubtless, in future, be much prescribed. It is a dilute preparation. There is one grain of iodine in four ounces of the liquor. An ounce would therefore be a very *safe* dose, but you may begin with a couple of drachms, and increase the quantity, if need be, gradually: for not only Dr. Manson, but Dr. Copland also, who states that the remedy has been very successful in his hands, advocates *small*, unirritating, what are sometimes called *alterative* doses. Simple friction is said to have had the effect of diminishing the tumour; and friction with some ointment or liniment containing iodine should be employed whenever the internal exhibition of the remedy is contra-indicated; or *in addition* to its internal use. There is an authorized form for that purpose also in the Pharmacopœia—the *Unguentum Iodini Compositum*. A small portion of this may be rubbed upon the tumour night and morning. Or the tumour may be painted, night and morning, with the compound tincture of iodine, pauses being made whenever the soreness of the skin may require them. The tincture stains the surface of a deep orange colour, so that during this process the throat must be kept covered.

Among anæmic young women, more or less fulness of the forepart of the neck, from slight enlargement of the thyreoid gland, is of very frequent occurrence. Sometimes the eyeballs are at the same time unduly prominent. In these cases, if you cure the anæmia, you will commonly cure the bronchocele also, or greatly diminish it: and I would recommend you to address your first remedies to the general rather than to the local ailment. If, when the blood has been replenished and the health improved by the salts of iron, and by other suitable means, the gland should still remain tumid, you may then resort, with caution, to the use of iodine. I need not add that besides great care in watching for the specific ill effects of the iodine upon the system, no less care is to be taken in correcting the state of any other function which may be faulty, and in improving the general health.

Such is the best *medical* treatment of bronchocele; and such are the plans which

you will always do well to make watchful trial of in the first instance. And with respect to surgical treatment I may observe, that so long as the disease is merely a deformity, so long as it does not interfere with any of the important functions of the body, nor produce serious discomfort — does not distress the respiration by pressing upon the trachea, nor impede deglutition by pressing upon the œsophagus, nor derange to any great degree the circulation through the head by pressing upon the great blood-vessels of the neck, nor grievously encumber the patient by its weight — we should not be justified (in my opinion) in performing or advising any surgical operation for the removal or the diminution of the tumour. Of such operations the three principal are, extirpation of the whole gland; the passing a seton through the tumour, and so exciting suppuration in it, whereby its substance is broken down and destroyed; and, tying the arteries which supply it with blood. The first of these methods, extirpation, has been performed when the wen was small; but few patients, under such circumstances, would consent to the operation; and few surgeons would now-a-days, I presume, advise or undertake it: and in cases where it might seem more expedient, that is, where the swelling is large, and suffocation is threatened by its pressure on the trachea, the execution of this measure would be exceedingly difficult and dangerous; for the arteries are so much dilated in these cases that perilous hæmorrhage might be expected from their division, especially when their close vicinity to the carotids is considered. Such large goitres come to involve also, by their lateral extension, very important nerves there situate. In one case where excision was attempted, the hæmorrhage was so alarming that the surgeon was obliged to desist in the middle of his task; and the patient actually died of hæmorrhage a few days afterwards. I believe that this operation may be considered as wholly abandoned by surgeons in the present day.

The introduction of a seton into the tumour has been more successful. This practice was revived about thirty years ago by Dr. Quadri, of Naples; who supposed, indeed, that he had been the first to devise it. You will find an account of his mode of proceeding in the tenth volume of the *Medico-Chirurgical Transactions*, by Dr. Somerville. The seton is passed through the substance of the gland, and retained there a considerable time; the chief caution necessary is to avoid the enlarged blood-vessels. Dr. Quadri affirms that the larger trunks of the thyreoid arteries will not be endangered, unless the seton needle be passed so deeply as almost to touch the thyreoid cartilage; and that hæmorrhage from any of the branches of those arteries that may be wounded when the seton is inserted more superficially, will not be attended with hazard. This plan was followed in one case by ulceration and sloughing, and the patient died. An example of the success of this treatment occurred in the practice of Mr. James, of Exeter; the tumour was almost entirely removed, and the patient was for some time in London for the purpose of showing himself to the medical men here. But he also had passed through a good deal of suffering and of peril.

The expedient of tying one or more of the thyreoidæal arteries, and so *starving* the tumour, has been attended with varied success. It has been done on the continent; and several times in this country: there is a case of it by Mr. Coates, of Salisbury, in the same volume of the *Medico-Chirurgical Transactions*. His patient was much relieved for a time, and supposed herself cured. But the tumour gradually returned, and caused her death by suffocation. Sir B. Brodie has also performed a similar operation: and I have myself seen one very satisfactory instance of the same thing, the operation having been done by the late Mr. Earle in St. Bartholomew's Hospital. The patient was a young woman with an immense bronchocele, which for some time previously had obstructed her breathing, and of which the effect on the trachea seemed to be every day increasing. There was loud wheezing, and great difficulty of respiration, and cough, and extreme emaciation: and it was plain that the girl must soon die strangled if nothing were done for her relief. One of the arteries, I think the superior thyreoidæal, was tied, without much difficulty, on one side. After the operation, the tumour on that side shrunk considerably; the distress of breathing was removed; and the patient presently recovered so much of her former strength, and flesh, and comfort, that she was unwilling to have anything more attempted, and left the hospital. After some time, however, she came back again of her own accord, and requested that the artery on the other side might be tied also. This was accordingly

done, and a further reduction of the tumour took place. The shrinking, however, if I remember rightly, was not so striking or complete after the second operation as after the first: but the patient was certainly rescued, upon the whole, from imminent death, and put into a condition of ease and at least temporary safety; the tumour that remained constituting merely a deformity. I never heard of her afterwards. In a case very similar to this, related by Mr. Crawford in the *Cyclopædia of Practical Medicine*, Mr. Wickham, of Winchester, tied one of the arteries, with much immediate, but no ultimate benefit. The goitre gradually diminished for about six weeks, and then (in consequence, I presume, of the establishment of a collateral arterial circulation) it as gradually enlarged again till it was as big as ever.

Of these surgical expedients there is not one, of which the *average* results have been sufficiently prosperous to warrant its repetition, except in cases where life is put in jeopardy or made miserable by the swelling; and where other methods, and particularly the treatment by iodine, have been tried, and have failed. One exception, perhaps, I should here make. The tumour sometimes evidently contains a quantity of fluid, either in one of its large cells, or in a distinct cyst. Now the cell or cyst, may in such cases be punctured, and the contained fluid let out, without much risk. This was done in one instance by my colleague, Mr. Arnott. He kept the orifice open; and the cyst shrank, and was at last obliterated, and the woman was much gratified by this diminution of her load. I have since met with a precisely similar case.

LECTURE XLIV.

Cynanche Parotidæa. Spontaneous Salivation. Aphthæ. Cynanche Tonsillaris.

THE Greek writers on medicine apply the terms *συναγχή* and *κυναγχή* to inflammatory affections occurring about the *throat*, and more or less interfering with the functions of respiration and deglutition: and the Latins employ the word *angina* in nearly the same sense. Cullen, in his *Nosology*, has made a *genus* of *Cynanche*, although the diseases which he has included in that genus have but little connexion, except that the parts they occupy lie *near* to each other. Some of them indeed have their seat in different, though almost contiguous, portions of the *same membrane*; and are apt, sometimes, on that account, to pass one into the other. In general they are allied rather by proximity of situation, than by community of symptoms.

I mention these things, because there being a great disposition in the present day to *re-name* diseases, and to affect a more precise and scientific nomenclature than sufficed for Cullen, if I adopted the more modern appellations without adverting to the old ones, which have been current so many years, you might experience some difficulty in your reading, in determining what disease was intended, when it was merely *named*. For my own part, I think there is much inconvenience in altering the established nomenclature; and especially in changing such arbitrary terms as, though they may not be *scientific*, are yet *definite*, and convey no erroneous notions respecting the nature of the disorder. I shall give you, however, in most cases, both the old and the new denominations.

Now one of the maladies in Dr. Cullen's genus *Cynanche* — though not the first in the order he follows — is *cynanche parotidæa*. It is an inflammatory affection of the salivary glands, and of the parotid gland in particular. Accordingly it is called *parotitis* now-a-days. It is not, however, mere inflammation of the parotid, arising from any cause whatever; and therefore parotitis, unless some epithet be added, is less exact than *cynanche parotidæa*. The vulgar have given it just as good an arbitrary name as the learned; and they call it in this country the *mumps*. With the Scotch it is, I believe, the *branks*.

This disorder need not detain us long. The parotid swells; tumefaction takes place beneath the ear; and if the submaxillary and sublingual glands are not impli-

cated in the outset, they soon participate in the tumefaction, in most instances; so that the swelling extends from beneath the ear along the neck, towards the chin, and the swelled parts are hot and painful, and very tender when touched. The aspect of the patient becomes curiously deformed. Sometimes one side only is affected; sometimes both sides at once; but most commonly of all, first one side and then the other. These local symptoms are attended with slight fever. But the only function that is materially affected is the motion of the lower jaw, which is impeded by the swelling. The inflammatory condition almost always terminates after a few days, in resolution, under the use of the antiphlogistic regimen, and the application of external warmth. The disease reaches its height in about four days, and then begins to decline; and its whole duration may be computed, on an average, at eight or ten days.

This complaint often prevails epidemically: when it affects one person in a family, or school, it usually affects several others, simultaneously or in succession. It chiefly attacks children and young persons. There can be no doubt that it spreads by contagion; and it seldom happens that the same person is twice affected by the mumps. These are remarkable circumstances, and give the malady a peculiar and specific character. I do not dwell upon them now, because they belong also to a very interesting *group* of diseases, which will require to be particularly considered hereafter.

Another curious circumstance connected with the disease, and one which has some bearing upon its treatment, is that, in many cases, upon the subsidence of the swelling of the neck and throat, and particularly when it subsides *quickly*, the *testicles*, in the male sex, become swollen and tender, and the *mammæ* in the female. It is said, but I do not know whether the observation be constantly true, that the testicle, or the breast, of the *same side* with the inflamed parotid, suffers. Sometimes the testicle wastes away after the swelling recedes; a circumstance which is known occasionally to happen when inflammation of that part arises from other causes. This, however, is not usual. In general the inflammation subsides and ceases in the one gland as it does in the other; the swelling is neither very painful nor long continued. But sometimes a more serious transference takes place, from the testicle to the brain: this I have never witnessed; but then, to say the truth, I have not often been called upon to treat the mumps, and my personal experience of it is limited. I find it stated that the metastasis to the testicle is considered as rather a fortunate circumstance, because it serves as a sort of protection against metastasis to the brain; but I suspect this to be a mistake. Inflammation of the brain, or of its membranes, has sometimes occurred on the disappearance of the *parotid* swelling; but it has much oftener supervened, I believe, upon the retrocession of the inflammation from the *testicle* or *mamma*. It is said also that the inflammation sometimes returns from the testicle to the parotid, and back again; oscillating thus two or three times between the two glands. Fortunately, the metastasis to the brain is much more rare than that to the testicle.

The treatment of the mumps is simple. It consists in the observance of the antiphlogistic regimen; mild diaphoretics; laxative medicines if the head aches, or the bowels are confined; and warm fomentations, or dry warm flannel, to the neck and throat. The tendency observed in this complaint to a change of place—to metastasis to more important organs—forbids us from using very active measures to *check* or *subdue* the inflammation. Nor are such measures necessary. We are not to bleed, nor violently to purge such patients, nor to apply cold to reduce the swelling. Luckily hot applications are not only the most safe and proper, but the most grateful also to the feelings of the patient. If suppuration should ensue—which is unusual and unlikely, but which sometimes does occur from extension of the inflammation to the neighbouring areolar tissue—poultices must be substituted for the fomentation. Warm applications, and rest in the horizontal posture, are to be recommended when the inflammation leaves the salivary glands, and attacks the testicles; or if the patient will not, or cannot, lie up, the testicle must be supported by a suspensory bandage—a bag truss. If the inflammation of the testicle or mamma be very violent, we must apply leeches, and afterwards poultices; but this will not often be required, or advisable. Finally, if the inflammation should fly to the brain, we must lay aside our previous caution, and treat the disease in that active manner which the inflammation of so important a part of the body demands. No *worse* metastasis *can* occur on the cessation of the phrenitis. I have fully spoken heretofore of the treatment to be pursued in that disease, and I have nothing to add respecting it now, except that it may

be right, as an auxiliary expedient, to try to reproduce the inflammation in the parotid, or testicle, or mamma, by irritating applications—mustard poultices, for example—in the hope of thus producing what is called *revulsion*, and of diverting the disease from the brain to the part which it previously occupied.

You know that there is another specific form of *parotitis*, which is apt to be induced by mercury. Of this I have already spoken. When it is severe, it may be treated by leeches, without any dread of such metastasis as occurs in the mumps. It is usually, though not always, accompanied by a profuse discharge of the secretion proper to the glands affected; and it is attended also by sponginess and swelling of the glands.

I presume that when inflammation of these salivary glands is *not* attended with ptyalism, the parenchyma of the gland, or the areolar tissue which enters into its composition, is principally affected; and that when there is much salivation, the membrane lining the secretory and excretory ducts is implicated. We see the same distinctions in other analogous organs.

Profuse ptyalism sometimes occurs without any obvious cause; and is then said to be *idiopathic*, or spontaneous: and this is a circumstance which it concerns you to be aware of, both as practitioners, and as medical jurists. The same *tenderness and swelling* of the salivary glands, the same copious *secretion and excretion of saliva*, nay, even the same *fœtor*, or a smell which can scarcely be distinguished from it—the same collection of symptoms which is familiar to you as indicating the specific action of mercury upon the human system—will arise sometimes (but very rarely) when not a particle of mercury has been administered. Several other substances are well known to have the occasional effect of producing an increased, and even a profuse flow of saliva: preparations, for example, of gold, of copper, of antimony, and of arsenic. The castor oil is said to have sometimes the same consequence. Digitalis certainly has; and the iodide of potassium; and sometimes, I believe, opium. Now and then ptyalism is met with as a symptom, among others, of pregnancy. Occasionally it results from some local irritation within the mouth; from a decayed or misplaced tooth. But what I principally wish to call your attention to is the fact that *salivation* may occur as an *idiopathic complaint*. In the twenty-sixth volume of the *London Medical and Physical Journal*, there is an instance of it described by Mr. Davies, in which two or three pints of saliva were discharged daily for some time. This flux at length ceased under the use of laxative medicines. In the second volume of the *Transactions of the College of Physicians* is an extraordinary example of the same thing, related by Mr. Power. A young lady, of sixteen, spat from sixteen to fourteen ounces of saliva daily, for upwards of two years. Mr. Power believed that the ptyalism in this case was originally excited by wool, which he found, in a fœtid state, in her ears. In the *Revue Médicale* there is an account given of a patient who was cured of a spontaneous ptyalism after spitting nine pints daily for nine years and a half. You may see another instance, as related by Dr. Prout, in the old series of the *Annals of Philosophy*. Dr. Pereira states that he has seen a dozen such cases; and he describes one which was fatal, not from the ptyalism however, but from sloughing of the cheek: and this is no uncommon circumstance. In certain cases of idiopathic inflammation and ulceration of the gums or cheeks, from some constitutional unsoundness, there may be extensive sloughing, ptyalism, and a very offensive odour, much resembling that which mercury produces. I have met with one example only of well-marked spontaneous ptyalism; and some of its circumstances were so peculiar, that they may be worth relating. I was taken out to Bayswater, by a medical friend, in the beginning of the year 1833, to see a little girl ten years old, who had been in a state of salivation from the 5th of November in the preceding year. Up to that time she had been a healthy, lively child, with nothing very remarkable about her, except that she was habitually subject to profuse perspirations, which had a very acid smell: so that the washerwoman was always aware which were her clothes, when she came to wash them, by this *smell*. She then suddenly became indisposed, had a little headache, and began to spit a good deal. This was noticed by her mother, and pointed out to her medical attendant, before *any* medicine was given her; and mercury, on that account, was religiously withheld. But in spite of all treatment the ptyalism went on increasing. When I saw her she was spitting three pints of saliva in twelve hours: transparent, rather dark-coloured, and with a small quantity of foam on its

surface. There was nothing amiss with her teeth, or her gums, and no fœtor of the breath. She was greatly emaciated, and resembled, in some respects, a person worn down by diabetes. From the very commencement of the spitting, the acid perspiration had ceased, and even the vapour bath failed to make her sweat. A great variety of remedies were tried under Dr. Nevins's superintendence, but without the least good effect. At last came the visitation of the influenza, in April of that year. The girl became severely affected by that disorder; and thereupon the salivation disappeared, and has not returned. I heard to-day that she is in excellent health.

Should you meet with cases of the same kind, you will search for some cause of irritation in the neighbourhood of the salivary glands, and especially in the state of the teeth and gums; and finding none, you will seek further for the cause of the salivation in some deviation from the natural condition of one or other of the principal functions of the system: and you will regulate your treatment accordingly. I do not know of any specific plan of cure to be recommended: but it is certainly of importance that you should be acquainted with the fact, that ptyalism sometimes exists as a separate and independent malady. Astringent washes are found, sometimes, of service; a solution of alum, or the infusion of catechu, or a few drops of creasote suspended, by the help of mucilage, in water.

Before I proceed to the diseases pertaining to the interior of the fauces and throat, let me take this opportunity of saying a few words in respect to *aphthæ*. They form the characteristic symptom of an especial disease of infancy: and they are apt to occur in the course of other diseases in adult age; and are then of some importance as guides in forming our prognosis, and even in determining our plan of treatment.

Aphthæ consist in small, irregular, but usually roundish white specks, or patches, scattered over the surface of the tongue, and the lining membrane of the cavity of the mouth and fauces; the angles of the lips, the cheeks, the palate, the pendulous velum, the tonsils, the pharynx. They look like little drops of tallow, or morsels of curd, sprinkled over those parts; they project a little above the surrounding surface; and, in fact, they are mostly formed by elevated portions of the mucous epidermis, covering a small quantity of a serous or gelatinous fluid, which separates the epidermis from the subjacent corium. These portions of the epidermis detach themselves, and fall off; leaving behind them a reddish raw-looking surface, or sometimes a foul and ash-coloured spot: and successive crops of these aphthæ are apt to be formed.

Now children in arms who exhibit these aphthæ, are said to have the *thrush*. This occurs at an early age; seldom, or never, I believe, after the period of lactation is over. The spots occasion some inconvenience in themselves—the mouth is rendered hot and tender by them. The child may be eager enough to take the breast, but is observed to do so with pain and wailing whenever the mouth is applied to the nipple, and attempts to suck or to swallow are made.

But these aphthæ, thus occurring in infants, are attended with other symptoms of disorder; such as drowsiness, sickness, diarrhœa, and some feverishness. And a general notion prevails, I believe, that the same aphthous condition which is visible in the tongue and mouth, pervades, in such cases, the whole of the alimentary canal. But this must be a mistake. That some morbid condition exists throughout that tract is highly probable, but true aphthæ can only form on those mucous surfaces which are provided with a continuous *epidermis*. This erroneous notion has been strengthened, perhaps, by the observation of aphthous spots on the pharynx and œsophagus. The complaint sometimes appears to be the result of improper diet, in children brought up by hand; or of milk of a bad quality, from an unhealthy or intemperate nurse. It generally lasts eight or ten days. It is not attended with much danger, except in certain cases, when the surface is left brown or bluish after the loosening and separation of the crusts. In such cases, the local affection is apt to run into a bad kind of gangrenous ulceration, and the discharges from the bowels become slimy and shreddy.

In almost all instances of the thrush in children, there is acidity of stomach present. Care, of course, is to be taken to discover and to correct any error of diet; and any unwholesomeness in the quality of the food. And *antacids* are to be administered. I know of no form of medicine better adapted to remedy the diarrhœa of infants, than the *Pulvis Sodæ cum Hydrargyro* of our hospital Pharmacopœia; composed of two

parts of the Pulvis Cretæ Compositus, two parts of the dried Carbonate of Soda, and one part of Hydrargyrum eum Cretâ. From three to five grains of this powder may be given thrice daily: and for the local affection of the tongue and mouth, the *mel boaris* is a capital application. It may be painted on the aphthous parts with a camel's-hair pencil.

Aphthæ occurring in adults, in the course of other diseases, are often the harbingers of dissolution. They denote considerable *debility*; and they point out the propriety of sustaining the patient's strength by bark, wine, and nourishing food. It is remarkable how treatment of this kind will sometimes *tell*. I had a patient last summer who lived for some months, and in tolerable comfort, after a second attack of apoplexy. Every now and then he would have a crop of aphthæ appear, which was always an admonition to us that he not only would bear, but that he required some tonic. A more generous diet, with bark, would dissipate them in a day or two.

Borax is an excellent application for aphthæ, whether they occur in adults or in infants. I have known it afford great comfort to patients who were in the last stage of phthisis, and to whom the aphthous state of the mouth was a source of considerable distress. Equal parts of Mel Boracis, and of Syrup of Poppies, make a good form. Or an agreeable as well as useful gargle may be made by mixing two drachms of Borax with an ounce of Mel Rosæ, three ounces of Decoction of Quince Seeds, and six ounces of water.

Aphthæ seem sometimes to depend upon mere derangement of the stomach. A nobleman who is well known as a *bon vivant*, can never eat shell-fish (so I am told by his physician) without finding, within two hours, that his mouth is full of aphthæ. Even lobster-sauce will serve him thus. I look upon this as a sort of internal urticaria.

[The disease of the mouth occurring in infants during the period of suckling, in which the tongue, and the inner surface of the lips and cheeks are covered, to a greater or less extent, with minute portions of a white matter resembling curd—and which constitutes the *muguet* of the French writers, the *thrush* or *children's sore mouth of nurses*, and the *aphthæ lactumina* and *aphthæ infantiles* of the older physicians, is evidently a very distinct affection from the *aphthæ* which occur in the adult as well as in the infant. The first depends upon an erythematous inflammation of the mucous membrane of the mouth, in which an altered secretion, in the form of small and curd-like particles or flocculi, or, as in other diphtheritic inflammations, of large patches of a soft pseudo-membranous matter, takes place upon the surface of the inflamed membrane. Upon the separation of these morbid exudations, the membrane beneath is found to be smooth, and without any solution of continuity. According to Guersent, the curd-like exudation is deposited beneath the epithelium, and its separation is consequent upon the rupture of the latter; Plumbe is of a similar opinion; Guyot and Billard, however, never saw it, excepting upon the surface of the epithelium, and this accords with our own experience.

In mild cases, the inflammation of the mouth quickly disappears, the particles of curdy matter becoming detached, fall off, and leave the membrane beneath of a smooth and healthy appearance. In other cases the inflammation continues for a greater length of time with little abatement: the spots of curd-like matter increase in number, and, occasionally, form by their union large patches, often of considerable thickness—these patches, sooner or later, become detached and fall off, and their place is quickly supplied by a new exudation: and this separation and renewal of the patches continue as long as the inflammation lasts. In some instances, the patches upon the tongue, lips, and cheeks, coalesce, and the whole of these parts become coated with a whitish, granulated crust, which not unfrequently extends into the fauces, pharynx, and, occasionally, into the larynx.

In situations where a number of children are crowded together, in ill-ventilated apartments, the patches of exudation acquire often a dark colour, the breath of the infant becomes fetid—the submaxillary glands enlarged and painful, the face swollen and of a dusky-red hue—the lips and gums become tumid, and bleed upon the slightest touch, while a fetid sanious saliva flows constantly from the mouth. Diarrhœa often attends, the discharges being dark-coloured and highly offensive. The disease, in its milder forms, is rather troublesome than dangerous—and it may be removed very speedily by an appropriate treatment; but when it is attended by the

symptoms last described, it is very apt to terminate fatally, death being occasionally preceded by a deep comatose condition.

There exists some difference of opinion among medical writers as to how far the morbid exudation characteristic of this affection extends beyond the mouth and fauces. It is generally admitted that, in severe cases, it has been found in the œsophagus, as far down as its cardiac orifice: but, while some, including Billard, have asserted that it has been observed throughout the whole tract of the alimentary canal, others, with Veron, maintain that, in no instance has it been met with beyond the the œsophagus—the curd-like crusts, occasionally found in the stomach being, as they suppose, conveyed thither from the mouth by deglutition. Guyot gives a case, in which the disease was detected, after death, throughout nearly the whole tract of the intestines. In the few opportunities we have had of examining the state of the alimentary canal in infants who have died whilst labouring under this disease, we were unable to trace the exudation beyond the œsophagus—a similar statement is made by Dewees and Eberle.

We are to recollect that the disease just described is the result of an erythematous inflammation of the mucous membrane of the mouth; while *aphthæ* are produced by a follicular inflammation of the same membrane. The latter affection is more commonly observed about the period of dentition than at an earlier age—it is particularly liable to occur in children of a lymphatic temperament, or in whom hæmaturia has been rendered imperfect, by improper or innutritious food, a damp and cold, or impure and stagnant atmosphere, exclusion from the light, and neglect of cleanliness. It is, also, of very common occurrence during most of the chronic affections, especially of the intestinal canal, in persons of all ages.

In the commencement of the disease the mucous membrane of the mouth becomes increased in redness, and upon the inner surface of the lips and cheeks, on the sides and inferior surface of the tongue, and, occasionally, over the greater part of the soft palate, there soon appear a number of distinct white specks, which, upon examination, are found to be small transparent vesicles, of a greyish or whitish colour, each being surrounded at its base by a raised, hard ring of a red colour more or less decided. These vesicles often occur in groups, or they may cover the whole of the lining membrane of the mouth and fauces; extending, in some cases, into the œsophagus, and throughout the alimentary canal; while in other cases they penetrate into the pharynx, and, according to some writers, into the larynx and even the trachea. The follicular inflammation will often continue for some time, as just described, without making any further progress, and it may often be arrested before ulceration ensues. Usually, however, the vesicles enlarge in size, rupture, and give discharge to a whitish matter; a superficial ulcer now occurs, with slightly elevated edges, and surrounded by a circle of inflammation. These ulcers often secrete a white, curdy matter, which adheres, at first, to their surface, but becomes subsequently detached, and is either swallowed or ejected with the saliva. It is often succeeded by a new exudation of a similar matter, and thus, in protracted cases, the crusts of curdy matter are repeatedly detached and renewed; or only a portion of the crusts are detached, while the general layer of curdy matter remains adherent, often for weeks. When the aphthous ulcerations are numerous, and in close contact, this curd-like exudation may spread from one to the other, and form a layer, often of considerable thickness and extent. Occasionally, the exudation from the ulcers is mixed with a small portion of blood; it then forms dark-coloured crusts, which have, not unfrequently, been mistaken for gangrenous sloughs.

Upon the subsidence of the inflammation the ulcerated follicles readily cicatrize without leaving any permanent scar.

Occasionally, particularly in children of debilitated habits, and who are deprived of proper hygienic influences, the aphthous ulcerations become gangrenous, their edges shrink, and assume a ragged, flabby appearance; a brownish slough forms in their centre, which, on separating, leaves a granulated surface of a vermilion hue; or, in place of a slough, the ulcers become covered with a brown, creamy fluid, that exhales a very decided gangrenous odour. The parts surrounding the ulcers become tumid, soft, and of a violet hue. From the half-open mouth of the child is discharged a ropy, often fetid, saliva. The countenance becomes pale and puffy; the pulse feeble; and the entire surface of the body pallid, and deficient in sensibility:—

repeated vomiting, profuse diarrhoea, and a tympanitic condition of the abdomen, generally occur; and occasionally, hiccup with frequent eructations, and the patient finally dies, according to Billard, without febrile reaction or cerebral excitement.

Recently, M. Gruby has attempted to show that, aphthæ and muguet are invariably produced by the development of a cryptogamic vegetable.

According to the researches of this gentleman, the affection consists, at first, of small, conical, whitish elevations, twenty-five millimetres in diameter, dispersed over the mucous membrane of the mouth. These elevations quickly augment in size, and extend rapidly over the adjacent surface, until, finally, the whole of the mouth, fauces, and sometimes the entire extent of the alimentary canal, appear to be covered with a pseudo-membranous layer, from two to three millimetres thick, and strongly adherent to the subjacent tissue. When a portion of this substance was examined under a microscope, M. Gruby found it to be composed entirely of a collection of cryptogamic plants, the roots of which, of a cylindrical form, transparent, and about one-four hundred and eightieth part of a millimetre in diameter, are implanted in the cellules of the epithelium. During their development, projections from these roots penetrate the entire series of cellules of which the epithelium is composed, to arrive at the free surface of the mucous membrane.

According to M. Gruby, these cryptogamic plants have considerable analogy with the sporotrichium described by some botanists. Being very fragile, they become detached by the movements of the tongue and lips, and mixing with the food, are carried into the alimentary canal, a considerable portion of the mucous coat of which they subsequently cover. Those children in whom this extension of the disease takes place to any great extent, fall into a state of marasmus, and soon die.

M. Gruby, having never detected in the white substance of aphthæ or muguet any thing else than the cryptogami just described, and the cellules of the epithelium,—there being, in no instance, any product of inflammation present,—considers himself authorized to conclude that aphthæ are neither more nor less than a vegetation occurring upon the living mucous membrane. Views precisely similar to those of M. Gruby have been advanced by Dr. Berg, of Stockholm.

Dr. Oesterlein has also submitted the matter of aphthæ and muguet to microscopic examination, and has been able to detect in it a vegetation similar to that described by the observers just named. This vegetation he has met with, however, only at the period of the fullest development of the aphthæ or muguet, which latter he considers to be the product of an exudation resulting from an inflammatory condition of the mucous membrane; the production of the confervæ being purely accidental. He attempted, repeatedly, to transplant them to other animal tissues or fluids, but without success.—(See *Condie on Diseases of Children.*)—C.]

Hard by the salivary glands lie the tonsils: and one of Cullen's species of cynanche is the *cynanche tonsillaris*: in more modern language, tonsillitis, or amygdalitis; or, in the vernacular, quinsy, common inflammatory sore-throat: a disease which, though internal, is yet within the reach of our sight, and easily recognised.

The popular term quinsy is in truth traceable—through the French *esquinancie*—to the scientific term cynanche.

This common and troublesome disorder occurs with very unequal severity in different cases. The differences depend upon the extent of the disease, and upon the number and variety of the parts which it involves: for it is seldom limited entirely to the tonsils, but spreads to the uvula, the velum palati, the salivary glands, the pharynx, and even to the root of the tongue, and the neighbouring areolar tissue. When the inflammation is superficial it does not produce any great distress, even though it may be diffused. When it penetrates through and beyond the mucous membrane, it is apt to end in suppuration, and to harass the patient much: the tonsils swell to an enormous size, and at length deep abscesses form in them. The disease is worst of all when the back part of the tongue, and the muscular and areolar tissues thereabouts, become implicated: it may chance to reach even the larynx, and then it is always and extremely perilous.

Under its more ordinary form, cynanche tonsillaris generally manifests itself, at first, by a slight degree of uneasiness and difficulty in swallowing; with a constant dryness and sense of constriction in the fauces, and a feeling as if some foreign sub-

stance were sticking there. Upon inspecting the throat, more or less of inflammatory redness and swelling is seen of one or both of the tonsils. Sometimes both of them are affected at once. Very frequently one only is first attacked: and the swelling begins in the other as it subsides in the first. This is just what occurs in many instances also of *eynanche parotidæa*. The uvula is commonly enlarged and elongated, and of a scarlet colour. Sometimes it drags upon the back part of the tongue, or dangles into the pharynx, causing the disagreeable sensation of a foreign body continually present, and provoking, by its mere contact, painful and fatiguing acts of deglutition. More frequently the uvula may be seen to be adherent to that tonsil which is most swollen. The dryness of the fauces soon gives place to a copious secretion of transparent mucus, which is frothy and viscid, and sticks to the inflamed surface, so as to be detached with difficulty; and the patient is tormented by continual and painful efforts to hawk up, or to swallow, this mucus. In an early stage of the disease, opaque whitish spots appear upon the red tonsil. There are exudations from its surface, or the discharged contents of the mucous crypts there situate. It is important that you should be aware of this, lest you mistake such specks for ulcerating or sloughing points, such as occur in some other affections of the throat, but which are not common in the outset at least of this.

When the inflammation is violent, the submaxillary and parotid glands sometimes swell, and become tender on pressure; and, less frequently, the patient is troubled by profuse ptyalism. In other words, the inflammation spreads from the tonsils to the salivary glands, and secondary parotitis occurs; sometimes with and sometimes without an augmentation of their natural secretion. Unable, or unwilling, to swallow the abundant saliva, the patient allows it to dribble from his mouth.

Now and then, although the act of swallowing is difficult and painful, you perceive, on looking into the fauces, no appearance which can account for these symptoms. The inflammation is seated lower down in the throat; out of sight. This cannot with propriety be called *cynanche tonsillaris*; indeed, it forms a distinct species, the *cynanche pharyngea* of Cullen. I mention it here because it really does not require any separate consideration.

The pain in *cynanche tonsillaris* is felt almost solely during the act of deglutition; which is difficult also from the mechanical narrowing of the passage by the enlarged glands. When both tonsils are affected at once, and much swollen, they push forwards the anterior pillars of the *velum palati*, and project in the shape of two great balls of flesh, into the arch of the fauces, so as to leave a very small space only between them; and they sometimes even meet and touch each other, and suffer ulceration from their mutual pressure. When attempts are made to swallow liquids, they are apt to return through the nose; the backward passage can no longer be shut in consequence of the tumid and fixed condition of the *velum palati*. The patients are unable to swallow even soft solids; indeed, the pain of swallowing is so great, that they are not easily persuaded to try. In severe cases pain shoots from the throat to the ear along the course of the eustachian tube; and this is considered important, as being indicative of suppuration. I believe that suppuration does occur in the majority of the cases which are attended with this symptom. Sometimes there is *tinnitus aurium*, and partial deafness, from the obstruction produced to the passage of air through the eustachian tube: either by closure of its extremity in consequence of the swollen state of the parts about it, or by some thickening of its lining membrane from an extension of the inflammation along its channel.

When the inflammation is intense, and involves the root of the tongue, the patient becomes unable to open his mouth sufficiently to allow the fauces to be seen; and the inflamed parts can be examined only by means of one's finger. In some instances the power of separating the jaws is so limited, as not to permit the introduction of the finger, and the tongue is incapable of any motion.

In ordinary cases, however severe the disease may be, there is scarcely any affection of the breathing. But the throat is so blocked up, and the free play of the *velum palati* so impeded, that the speech is altered; becoming thick, guttural, and inarticulate. You may often recognise the disease by the peculiar sound of the patient's voice, without looking into his throat. When the swelling of the tonsils is very great, the breathing does sometimes become impaired; and it is in such cases alone, or nearly in such cases alone, that this disease is at all alarming.

Cynanche tonsillaris is commonly attended, from the very outset of the inflammation, by smart inflammatory fever, severe headache often, and a rapid pulse, rising to 120 beats in the minute, or more. The constitutional disturbance runs higher than we might have expected, considering the limited extent of the local inflammation, and the comparatively small importance of the part inflamed. At the same time there is very little of that debility and anxiety which are observed, as we shall see hereafter, in common continued fevers.

The inflammation often terminates by resolution; but when it is violent or long-continued, it very frequently leads to the formation of pus. When the mucous secretion increases in quantity, and becomes less viscid, while the difficulty of swallowing diminishes, and the febrile symptoms decline, resolution may be expected. Suppuration, on the other hand, may be looked for when the inflammation is unusually intense; when, by the swelling of the tonsils, the breathing is impeded; when a pulsating pain is felt, shooting to the ear; when the patient can scarcely open his mouth, or protrude or move his tongue; when there is more than usual external swelling; and when the symptoms increase, or even fail to remit, after five or six days have elapsed. Rigors sometimes accompany and announce the suppuration: and afterwards the pus often may be seen shining through the membrane covering the tonsils. In many cases, however, it lies so deep that it cannot be detected by the most careful examination. At length the little abscess bursts; and the relief thereupon experienced by the patient is sudden and striking. All at once the pain ceases; he can swallow, and he feels himself well; and often indeed he is well, or nearly so. The matter discharged has always a nauseous taste and a remarkably foetid smell: and sometimes the fœtor, or the ill taste, is the only sign, besides the improvement in the symptoms, that indicates the rupture of the abscess; the pus being so small in quantity as, when mixed up with other matters, easily to escape notice; or (what frequently happens), passing backwards into the stomach, under an involuntary movement of deglutition. Suppuration sometimes, but rarely, takes place externally, in the areolar tissue of the neck, as well as internally.

The termination in gangrene is spoken of in books: and it is just possible; but it never happens, I imagine, except in unhealthy constitutions; or when tonsillitis occurs as a complication of more general disease, such as scarlet fever. It is much more common to see repeated attacks of cynanche tonsillaris produce what used to be absurdly called scirrhus, a permanent enlargement and hardening of the tonsils. While they are in this state, a low kind of inflammation is very readily re-excited in them. The enlarged tonsils are generally irregular, and notched; something like the surface of a walnut shell; and a white or yellow secretion is often to be seen lying in the hollows. This appearance may easily be mistaken, by an inexperienced eye, for ulceration.

There is not much risk of your confounding cynanche tonsillaris with any other complaint. The various species of cynanche enumerated by Cullen are separated each from the others, by certain broad lines of distinction: all derived, however, from different combinations of two symptoms; — *dyspnœa* and *dysphagia*. Thus, in cynanche tonsillaris, deglutition alone is difficult; and when you look into the throat, you see at once why it is difficult. There is equal difficulty of swallowing, and equal freedom of respiration, in cynanche *pharyngea*: but the cause of the dysphagia is not visible. In cynanche *trachealis*, the respiration is much affected; the facility of swallowing not affected at all. In cynanche *laryngea* both these functions are implicated; there is difficulty of swallowing, as well as difficulty of breathing. Cynanche *parotidæa* is distinguished by the *absence* of both the symptoms; its title to the name of cynanche is therefore equivocal. Many of these points will soon come under our notice again.

Cynanche tonsillaris is supposed to be most frequent among the young and plethoric. But it certainly occurs very often also in persons who are pale, and spare, and feeble; and in those of middle age. Some individuals appear to have, by nature, a strong predisposition to the disease; and in them its attacks are more or less periodical; recurring at particular seasons, and commonly during the variable weather of spring and autumn. The peculiarity runs sometimes in families. The liability to the complaint is also very much increased by repetitions of the attacks.

The only exciting cause worth mentioning, almost the sole cause indeed, is expo-

sure to cold. Not unfrequently it assails so many persons at the same time as to be epidemic; and for that reason it has sometimes been thought contagious. But it has no contagious property whatever. Although we often see several members of the same family affected by it at once, yet we may learn, upon careful inquiry, that its commencement in the different cases has been too nearly simultaneous to admit the supposition of its having been communicated from one to another. The patients have all been exposed to the same unwholesome influences, which operating upon similar constitutions, such as those who are sprung from the same parents may be expected to possess, have produced similar effects. This prevalence of the disorder at certain times and places, is connected, no doubt, with some peculiar conditions of the atmosphere.

The prognosis is almost always favourable. Not but what death may be produced by this disease, under peculiar circumstances, and when the inflammation is unusually violent and extensive. The late Dr. Gregory, of Edinburgh, used to mention in his lectures one instance, the only one he had met with among many hundred cases, of death from cynanche tonsillaris. He did not see the patient till he was moribund; and he suspected that it was combined with typhus fever. The only fatal case that I ever witnessed, occurred some years ago at the Middlesex Hospital, in one of my own patients. He was a stout young man, 26 years old, a private coachman. The complaint was clearly traced to his having got wet through, more than once, a day or two before it came on. Besides the ordinary symptoms of cynanche tonsillaris, there was great external swelling on both sides of the throat, and the patient was unable either to open his mouth, or to move his tongue. The inflammation involved not the tonsils merely, but the base of the tongue, the salivary glands, and the surrounding areolar tissue. At length suppuration took place. The abscess broke internally, and pointed also externally, just below the symphysis of the chin, where it was opened with a lancet. Two days after, there was a sudden gush of blood from the mouth. So immovable were his jaws that it was impossible to determine from which side the hæmorrhage proceeded; it was stopped, however, apparently by the treatment adopted. A fortnight later, the bleeding recurred profusely. It was now evident that the blood was arterial, and that it came from the left side of the throat. Preparations were made for tying the common carotid on the left side; but just as the operation was about to be begun, the patient expired in our presence. His death was shocking, but full of pathological interest. He did not sink, as you may have supposed, in the way of syncope, from loss of blood; but by suffocation. The blood passed down the trachea and into the lungs; and he had been so weakened by the previous hæmorrhage, that he could not expel the blood thus introduced, which actually choked him. A large clot was afterwards found, filling up the wind-pipe. I felt this man's pulse beat firmly and regularly, for a minute perhaps, after his last effort to breathe. On examining the body it was discovered that the abscess had opened internally behind and below the left tonsil. The lingual branch of the carotid artery crossed the site of the abscess; and had been severed and laid open by ulceration. From this vessel the fatal hæmorrhage had come.

It should be borne in mind also that cynanche tonsillaris does sometimes, by extension of the inflammation to the neighbouring parts, superinduce that very formidable species of cynanche, of which I am soon to speak, the *cynanche laryngea*. All cases in which the *breathing* is in any degree affected, should excite suspicion, and strict scrutiny; although the dyspnœa may be produced by the mere swelling of the tonsils.

You will understand, then, that cynanche tonsillaris *may*, under unusual and untoward circumstances, prove a fatal disease; but that it is so very rarely indeed. In almost all cases we may say that the life of the patient is not in danger.

In the uncomplicated and milder form of the disease, when the inflammation is superficial and the fever slight, no great activity of *treatment* is requisite. The patient should be kept within doors, and even in bed: for a troublesome tendency to a recurrence of the disorder may be fostered by neglect or imprudence. Cooling saline purgatives will be proper, and the antiphlogistic regimen. A strip of flannel may be put round the neck, and some stimulating embrocation applied to the exterior of the throat, beneath the ramus of the jaw: the compound camphor liniment is well adapted to this purpose. Some such plan as this will generally suffice, not indeed to

stop the inflammation of a sudden, nor to put an end at once to the fever, but to cause the complaint to run its course evenly, and to go on to resolution in a few days. Commonly it is not completely over until both the tonsils have been attacked in succession.

When you catch the disorder in its very outset, I believe you may sometimes succeed in cutting it short by an emetic: a scruple of ipecacuanha, for example, with a grain of tartarized antimony. In all cases it is right to administer a brisk purgative.

A great variety of astringent, acid, and other gargles, have been employed in this disease; and their good effects have, I apprehend, been much overrated. Many cases would do quite as well, or better, without them: for in the early stages strong astringents, and the straining and movements of the throat that accompany their use, may even be hurtful, and increase the pain and the inflammation. The only gargle which I should consider admissible in the commencement of the malady is a gargle of warm milk and water. I have known of one instance in which quinsy suddenly attacked a gentleman who was extremely anxious to use his throat, in public speaking, the next day. He occupied himself perpetually for some hours in this sort of fomentation of the tonsils with hot water; and with such good effect, that on the day following he was able to accomplish his object. Still there are cases in which, at certain stages of the disease, detergent gargles are serviceable, by assisting the excretion of the mucus that collects in the fauces, and by correcting fœtor. A weak solution of chlorine in water answers well. In more chronic sore-throats, stimulating gargles may often be employed with advantage. When the inflammation is violent, a slightly stimulant linctus is preferable; it *cuts the phlegm* as they say, *i. e.*, it promotes its detachment and removal. Of this kind, current jelly is one of the best.

But far better than anything else, as a local application to the inflamed fauces, is the steam of hot water; whether we are hoping for resolution of the inflammation, or whether we desire to promote and hasten the process of suppuration already begun. The inhaler introduced by myself into the Middlesex Hospital, and elsewhere, though somewhat clumsy in appearance, is the most convenient and effectual that I am acquainted with. I show it to you. It was invented in Edinburgh by a friend of mine long since dead, Mr. Hercy. It will stand upon a table, or lie upon a pillow; and a large volume of steam is carried inwards against the fauces by the mere natural breathings of the patient. Most of the inhaling machines that I have seen require a sucking effort, like that made in smoking a pipe: an effort that is apt to be irksome and fatiguing, especially in pulmonary diseases; for some of which this method of applying vapour directly to the suffering part is as useful as it is for sore throats.¹

FIG. 33.

Blistering the outside of the throat is a favourite remedy with many. When early applied, a blister often does much good, and probably prevents suppuration in some cases. But I have found blisters of uncertain efficacy; they leave a mark which lasts for some time, and which patients of the other sex are apt to complain of. For these reasons I prefer mere rubefacients; the liniment I mentioned before, or the compound soap liniment, or a mustard poultice folded between two layers of thin linen.

In more severe cases leeches applied to the upper part of the throat, just below the angles of the jaws, have been found to give sensible relief: and in the worst degrees of the disorder, when there is much outward swelling, and the jaws and tongue are fixed, leeches are absolutely requisite. It may be proper to take blood from the arm also. The necessity for active depletion must be measured by the severity of the local symptoms, the intensity of the fever, and the general strength and condition of the patient: and of these things a little experience will teach you to judge.

It is not to be expected that either leeches or blisters will be of much use after the process of suppuration has commenced; nay, they may sometimes be injurious by

¹ It would be wrong not to state here that Mr. Squire, of Oxford-street, has devised an inhaler which, combining the advantages of Mr. Hercy's, is less clumsy in form, and as convenient for use.

retarding it. It is frequently a difficult matter to determine whether pus has yet formed or not.

I have already admonished you to make a careful examination of the throat, and to watch your patient narrowly, whenever he experiences any difficulty of breathing. Dyspnoea may be produced by the mere swelling of the inflamed part: and when it concurs with much enlargement of the tonsils you had better pierce them with a lancet. If they contain matter, it will be evacuated; and if not, the bleeding produced by the puncture will generally reduce the swelling somewhat, and relieve the patient. There is an instrument made on purpose for this small operation, consisting of a lancet enclosed in a flat silver sheath, from the end of which it is made to protrude, to a certain extent only, by pressing upon a spring. The instrument should be directed towards the centre of the fauces, and not outwards; in order to avoid wounding important vessels or nerves. Dr. Cullen indeed says, "this does not require much caution:" but notwithstanding this high authority, I must warn you that puncturing or scarifying the tonsils is an operation not to be carelessly, or rashly, or wantonly performed. Portal mentions a case in which a skilful surgeon in scarifying the tonsil of his patient, wounded as he supposes some ramification of the internal carotid, and the patient was presently dead. The artery lies, as you know, very near the tonsil; and only a few years ago, in Ireland, it was struck by a surgeon while scarifying a gentleman's tonsil; and the gentleman died in three minutes. This I was told by the late Dr. Barclay. The case I related just now of fatal hæmorrhage from the lingual artery points to the same danger: and since that case occurred two others involving similar hazard have fallen under my own notice, and impressed me with a strong feeling of the necessity of caution. A man was brought into the hospital with profuse hæmorrhage from the right tonsil or its immediate neighbourhood, the consequence of syphilitic ulceration of those parts. He had lost three or four quarts of blood and was nearly dead. His life was saved by Mr. Mayo, who tied the common carotid on that side.

Last February (1838) a boy, from Harrow School, was placed under my care, in whom cynanche tonsillaris came on during convalescence from scarlet fever. So much swelling was there of both tonsils, that they met, and pushed the uvula outwards before them, and the breathing was much impeded. A surgeon who was in attendance with me punctured the tonsils. The next day a good deal of hæmorrhage took place; and this recurred several times, to a considerable and even an alarming amount. When the clots that formed were wiped away with a sponge, the blood could be seen welling out in a little stream, with a pulsating motion, from a small incision in the left tonsil. After much trouble and anxiety, the hæmorrhage was ultimately arrested, by applying a pencil of lunar caustic freely, within the bleeding orifice. Lint, wetted with the muriated tincture of iron, or with a saturated solution of alum, is a fit application in similar accidents.

Mr. Lawrence, who saw this case, told me that he once knew a patient die of hæmorrhage from the tonsillar artery.

I ought, perhaps, here to add, that Mr. Joseph Bell, of Barrhead, has strongly recommended the internal administration of powdered guaiacum, in large doses, as being almost specific in the cure of cynanche tonsillaris. He gives as much as half a drachm, suspended, by means of mucilage, in a draught, every six hours. Mr. Bell has no doubt that this remedy, if timely administered, will cut the disease short in ninety-nine cases out of a hundred. It has been found successful in other hands also. I have never had an opportunity of trying it.

The chronic enlargement of the tonsils, to which I have already adverted, is sometimes productive of great inconvenience and distress, and even of danger. Its occasional consequences are—habitual trouble in swallowing; confused and inarticulate speech; deafness in various degrees, from occlusion of the eustachian tubes; more or less impediment of breathing; and even spasm of the glottis and impending suffocation. The enlargement may in such cases be somewhat reduced, I believe, by repeatedly passing a stick of lunar caustic over the surface of the tonsils; or by repeatedly painting them with the compound tincture of iodine; but a much readier and a preferable plan is to amputate them, in part at least. This may be done by a ligature; or still better by scissors, or by a sort of small guillotine invented for that purpose.

It is not a very painful operation. Mr. Arnott removed one lately from one of my hospital patients; and but a very few days ago (December 1838) Mr. Mayo brought two, in a piece of paper, to the hospital. He had just before cut them off for a patient whose respiration they had much embarrassed.

[HYPERTROPHY OF THE TONSILS IN CHILDREN.—In young children the tonsils are subject to a chronic enlargement, the effects of which are far more serious than the entire neglect which the affection has met with from medical writers would lead us to suspect. In many cases there is no doubt that the enlargement is due to a sub-acute inflammation of the tonsils; in general, however, it would seem to be dependent simply upon the irritation of teething. It is commonly developed in children between six months and two years of age, thus coinciding with the most active period of dentition. In proof of the enlargement being due to the irritation of teething, M. Robert, who has examined the subject with some care, (*Bull. Gen. de Therapeut.*, May, 1843) remarks, that he has seen the evolution of the *dens sapientia* in the adult attended with a similar inflammation and hypertrophy of the tonsils.

The enlargement is always in both tonsils, and becomes, in many cases, very considerable. When of any extent it affects the voice, giving to it a peculiar nasal tone, and, by its pressure on the Eustachian tubes, impairs in a great degree the sense of hearing. By forcing up the *velum palati*, it also interferes with the freedom of respiration, hence those affected with it sleep with their mouths open. They are affected likewise with a constant troublesome dry cough; and the air in respiration being prevented from passing through the nares, causes the nose to remain undeveloped in breadth, and the anterior part of the face thin and, as it were, pinched. The most important result, however, of the enlargement of the tonsils is a flattening of the chest, to which Dupuytren first directed attention. This flattening M. Robert supposes to be produced by the enlarged tonsils preventing a sufficient quantity of air being admitted at each inspiration, sufficiently to fill the chest, or to cause from within the lungs a pressure equivalent to that of the atmosphere without. The deformity once established, it necessarily gives rise to dyspnoea, palpitation, and the usual results of interrupted respiration and circulation; hence the children in whom it exists are commonly pale, thin, and feeble.

When enlargement is once established, the hypertrophied tonsils never diminish in size; their excision consequently is the only means by which the inconvenience and injury resulting from their presence are to be remedied. For diminishing the deformity of the chest, M. Robert suggests various plans and different forms of gymnastic exercises.

Recently the application to the enlarged tonsils of the iodide of zinc, is said to have the effect of causing their rapid absorption. The article is prepared by placing a clean plate of zinc over a jar or vial, and sprinkling iodine over it. In a short time the iodide is deposited in the vessel, in the form of a semi-fluid deliquescent substance. This is to be applied pure, to the surface of the enlarged tonsil, by means of a camel's-hair pencil, or a piece of sponge, secured to a suitable handle. It is to be held on for a short time, and repeated every two or three days, until the object is accomplished. The application is followed by a pungent smarting, which lasts for twenty or thirty minutes, but by no other inconvenience. Dr. Goddard, of this city, we are informed by Dr. Parrish, in his annual Report on Surgery, read to the College of Physicians, has used the remedy extensively, and speaks very favourably of its effects. He has found it to possess the property of inducing a rapid absorption of the enlarged tonsil, by a sort of shrivelling process, without the formation of a slough. It does not, like the chloride of zinc, spread to the surrounding healthy structure, and hence, may be used without the fear of injury from being swallowed. (*Summary of the Trans. of the College of Phys., of Philadelphia*, No. vii, page 191.)—C.]

LECTURE XLV.

Acute Laryngitis. Symptoms. Treatment; Blood-letting. Tracheotomy, Mercury, Antimony. Anatomical Characters of the Disease. Causes. Secondary Laryngitis. Edema of the Glottis. Chronic Affections of the Larynx.

THE disease of which I have next to speak is of far more serious character than those which were considered in the last lecture. *Cynanche laryngea*, or acute laryngitis, has proved rapidly fatal in a large proportion of the instances in which it has been known to occur. Yet when the patient is seen tolerably early, and the nature of the malady is clearly perceived, and the source of peril thoroughly understood, I believe that our art is sufficient, in most cases, to rescue the sufferer from the fate that hangs over him. It is of the greatest importance, therefore, that you should be able to recognise laryngitis when you meet with it, and that you should comprehend the principles according to which it requires to be treated.

What is laryngitis? It consists, as the term implies, in inflammation of the parts composing the larynx; and especially of the mucous membrane that covers the laryngeal cartilages, including the epiglottis. The inflammation may be, and sometimes is, exactly limited to the larynx; but frequently it extends also to the posterior fauces, the velum palati, and the tonsils.

The *symptoms* of acute inflammation of the larynx are these. The patient complains of *sore-throat*. If you look into his throat you will commonly perceive some redness of the velum and uvula, and of the fauces generally. But there is a degree of restlessness and anxiety about the patient more than proportionate to the apparent inflammation. Among the earliest of the symptoms that bespeak danger, and ought to excite alarm, is *difficulty of deglutition*, for which no adequate cause is visible in the fauces; and to this is presently added *difficulty of breathing*, for which no adequate cause can be discovered in the thorax. The mode and character of the respiration are peculiar; it is attended with a throttling noise; the act of inspiring is protracted and wheezing, as though the air were drawn in through a dry, narrow reed. If you ask the patient what is the *seat* of his distress, *where* the disease is situated, he points with his finger to the *pomum Adami*. If he cough, he coughs with a peculiarly harsh, stridulous, husky, abortive sound. He either speaks quite hoarsely, or (what is more common,) all power of audible voice in the larynx is lost, and he speaks by means of his lips and tongue only, in a whisper. There is tenderness of the laryngeal cartilages; they are painful when pressed externally. The face is flushed; the skin hot and dry; the pulse hard. As the disorder advances, the patient's general distress increases: but some of the symptoms alter: his countenance becomes pale or livid, anxious and ghastly; his eyes protrude; he is miserably unquiet, impatient for some relief, declares or makes signs that he wants air, and begs that the windows may be opened; and if he does not *obtain* timely relief, he perishes—he dies strangled.

The pathology of this terrible disease is extremely simple. The membrane covering the interior surface of the instrument of the voice suffers inflammation. One effect of inflammation in mucous membranes is a thickening of those membranes; they become turgid and swollen. Another frequent effect is the effusion of serous fluid in the subjacent areolar tissue. By such tumid thickening of its lining membrane, the chink called the *rima glottidis* is narrowed: it is still further diminished in breadth whenever the membrane is lifted and protruded by infiltration of the tissue beneath it: it is so nearly closed up, that air cannot pass inwards in sufficient quantity to sustain the vital functions: a small portion only of the blood returned to the lungs from the right side of the heart undergoes the requisite change from venous to arterial. The miserable patient grows drowsy and delirious, and dies by a slow process of strangulation. If the rima glottidis become *quite* closed up, his sufferings, and his life, are quickly at an end.

This disease affords a good instance of a truth which was announced in a former

part of this course of lectures; viz., that the *danger* of a morbid change may depend entirely upon its situation. It is so, eminently, with laryngitis. The inflammation is sometimes limited to a spot of membrane not bigger than a square inch. If a square inch and no more of the same membrane, a little lower down in the trachea, were inflamed in the same manner and degree, the complaint would be quite unimportant. Cynanche laryngea derives all its peril from the circumstance that the inflammation tends to shut up what may be called the *janua vitæ*. The part affected subserves two purposes; it is the organ of speech; and it forms a portion of the channel through which air is conveyed from without into the lungs. Both of these purposes are impeded in laryngitis. Now the animal function of speech may be entirely and permanently suspended without any danger to life. The function of respiration, which, though under the influence of the will, is an organic function, will not bear to be *suspended*, even for a few minutes; and life cannot be *long* sustained when it is *much impeded*.

The difficulty of swallowing is a remarkable symptom, and almost always present. Yet it is not absolutely universal; for Mr. Lawrence describes a case in which it did not occur. It appears to result, in some measure, from the tumid and tender condition of the whole membrane which is common to the larynx and pharynx, and which is pressed upon as the larynx rises in the act of deglutition. But this symptom depends also, and in a greater measure, upon the state of the epiglottis, which is often enlarged, and fixed by the swelling in an erect position, and unable to execute its natural valvular office: so that when the patient makes efforts to swallow, a portion of the food or drink gets into the larynx, and a paroxysm of choking dyspnœa ensues. By pressing down the back part of the patient's tongue, and getting him at the same moment to make a coughing effort, you may sometimes obtain a sight of the tumid, red, and upright valve.

The dyspnœa is constant: yet there are pauses of comparative ease and quiet; and there are, commonly, periods of severe aggravation and urgent distress. It is probable that the permanent narrowing of the chink by the inflammation and its consequences is from time to time increased by a spasmodic contraction of the muscles that close the glottis.

This is the first disease that has come before us, in which the respiration has been *primarily* impeded. If you call to mind what was stated in one of the early lectures respecting death by apnœa, you will be at no loss to understand the manner in which life is destroyed in laryngitis.

This formidable malady has always existed; for you may trace examples of it, under various names, even in the writings of the ancients. But it is only in recent times that it has been singled out from the rest of the anginæ, and made a separate object of study. It has numbered some distinguished medical men among its victims: Dr. David Pitcairn, Sir John Macnamara Hayes, Sir George Tuthill. The celebrated General Washington died of it. When it has caused death it has generally run a rapid course, and proved fatal before the fifth day. It *has* carried the patient off in less than twelve hours.

It is of the utmost consequence to make an accurate diagnosis. Laryngitis is easily distinguished from cynanche tonsillaris by the extreme and peculiar dyspnœa which attends it. There may be difficulty of breathing in the latter disease, from enormous swelling of the tonsils; but then such swelling will mostly be *visible*. In laryngitis, the marks of inflammation to be *seen* on inspection of the fauces are generally slight and trifling, and quite inadequate to explain the difficulty of swallowing. Do not, however, forget, that laryngitis may *supervene* upon cynanche tonsillaris. Again, cynanche laryngea is readily discriminated from cynanche pharyngea; in which complaint there is great pain and difficulty in deglutition; but the breathing is quite free. In cynanche trachealis, or croup, which I shall next describe, the breathing is affected, and the swallowing is *not*.

What is to be done for a patient labouring under acute laryngitis? How and when are we to employ the great remedy for acute inflammation — blood-letting? or are we to employ it at all? These are points concerning which it is quite necessary that your minds should be prepared and prompt to decide. If you look merely to the results in the recorded cases of this fearful complaint, you will scarcely find an answer to the question. In some of them, copious bleeding appeared to save the patients;

in others, it was of no service, but rather seemed to accelerate their death. Sir John Maenamara Hayes suffered two attacks of cynanche laryngea. In the first he was freely bled. Dr. Roberts, of Bishop Stortford, informs us that the first bleeding was attended with *considerable relief*; the second also with *manifest advantage*; and by the third, *his safety appeared to be insured*. Fifteen years afterwards he died of the same disorder, for which he was again bled and leeches, under the care of the late Dr. Baillie. Washington was largely bled, and died. Again, Dr. Francis, of New York, recovered from acute laryngitis after copious venæsection, and still survives, enjoying a well-won reputation, in that city. It is evidently needful to consider and determine the circumstances under which we are to use, or to withhold, the lancet.

Bleeding, to be serviceable, or safe, must be performed *early*. There is, perhaps, no disease in which the *καιρός αὖρις*, the fleeting opportunity, is more conspicuous than in this. When I say that you must bleed early if at all, I do not mean that you are to reckon so many days or hours from the commencement of the disorder; but you must ascertain what progress it has made; for it travels sometimes at a railroad-pace. You must look to your patient's actual condition; and I apprehend that your practice, in respect to blood-letting, may be safely guided by the following rules. When there is high inflammatory fever present, and the skin is hot, the pulse firm and full, and the cheeks are red, and the lips florid, you may bleed your patient with decision and advantage. But if his powers are beginning to sink under the poisonous influence of imperfectly aerated blood, if his skin be cold, or even cool, his face pale or leaden, his lips blue, his pulse small and feeble, his mind wavering—you will do no good by blood-letting: nay, you will increase the debility which already exists, and hasten the fatal catastrophe.

With regard to *local* blood-letting, and to counter-irritation, there is one remark made by Dr. Farre of much practical importance. It is a common practice in affections of the throat, to apply leeches over or near the laryngeal cartilages, and afterwards to place a blister there. Now serous infiltration of the neighbouring parts often follows leech-bites; and the effect of a blister in producing serous effusion often extends beyond the skin; and the cartilages of the throat lie very near the surface: and it is possible that oedema of the glottis might be produced, or augmented, in consequence of these topical remedies. It will be better, therefore, when we wish to take blood locally, to take it by cupping from the back part of the neck: and when we desire to produce counter-irritation, it will be prudent to lay a blister on the upper part of the sternum, rather than to the front of the throat.

In the advanced stage of the disease, *medicine*, I fear, can effect but little.

But *surgery* may be more successful.

The danger arises from the *mechanical* obstacle to the entrance and exit of air into and from the lungs; and this state of peril admits of a *mechanical remedy*. If an artificial opening be made between the obstructed part and the lungs, the air is again freely inhaled and freely expelled; the blood undergoes the vital change from purple to scarlet; and the patient is placed in a condition of safety. He continues to respire through the hole thus drilled in the trachea, until the inflammation of the larynx has subsided; the thickening of the membrane disappeared; the submucous infiltration been re-absorbed; and the vocal instrument been restored to its natural integrity: and then the aperture in the windpipe may be suffered to heal, and the patient will again draw his breath through its natural channels.

This is one of the triumphs of the healing art. It requires a knowledge of the general *pathology* of the disease, *i. e.*, an acquaintance with the facts that acute inflammation may affect the larynx almost exclusively, and that its tendency is to narrow the fissure of the glottis, and destroy life by suffocation. It requires a knowledge of the *symptoms* of such inflammation: and it requires an accurate knowledge of all the essential circumstances of the particular case. For it is not every case in which the transit of air through the slit in the larynx is hindered, that is a fit case for the operation of tracheotomy. Some years ago there was brought to me by a surgeon, a man breathing with considerable labour and constraint, the air passing through the larynx with an audible hissing noise. The surgeon wished to know my opinion of the propriety of opening the patient's windpipe. He had come to the conclusion that there was ulceration of the membrane lining the larynx, with thickening;

that the cause of the sibilous respiration was partly meehanical, partly spasmodic; the little museles that close the glottis aeting with injurious energy in consequence of the neighbouring irritation: and he thought that this mischief in the larynx would have a better chance of being repaired, if the funetions of the organ could be for a time suspended. He was aware, however, of the necessity of ascertaining what was the condition of the *lungs*; and he had not studied auscultation long enough to trust his own ear in that matter. The patient was pale and thin, and emaciated; and three minutes sufficed to convince me that his lungs were extensively disorganized. His respiration was not so difficult as to threaten suffocation; he was not dying of the laryngeal obstruction; and I recommended that he should not be subjected to an operation which might eurtail his existenee, but could not effect a cure. The man died soon after: and we examined his body together. There was, as my friend had supposed, ulceration of the membrane near the *chordæ vocales*, and the lungs were full of suppurating or softening tubercles. I mention this case to show you that it is necessary to ascertain the condition of the thorax generally, before we perform or sanction such an operation as tracheotomy. Not that there is anything very formidable, or painful, or dangerous, in the operation itself. But if we cut a hole in a patient's throat, who is sure to die soon after of some other incurable complaint, we shall incur the risk of being charged with having killed him. Do not misunderstand me, however. If a patient's *life* be threatened by acute laryngitis, or by laryngeal œdema, and we are sure of that, and if at the same time we are sure that he carries another mortal disease about him, we are not for that reason to let him die, if we can help it, of the *laryngitis*; any more than it would be lawful for us to administer a drachm of prussic acid to a man condemned to be hanged the next morning. But we must state the whole of the case plainly to the patient's friends, and propose the operation as a mode not of effecting an absolute cure, but of staving off the *immediate* danger.

And here let me repair an omission of which I was guilty when speaking just now of the diagnosis. My object was to guard you against mistaking laryngitis for some other malady: but I must also warn you against the converse error, that of mistaking some other malady for acute laryngitis. I can assure you that such a mistake has been made; and tracheotomy has been performed, too, when there was no disease in the larynx; and the practitioners by whose authority it *was* performed have been ungenerously reproached for their error, although no harm beyond the slight pain and inconvenience of the operation resulted from it. The cases in which this blunder has been committed have nearly all, I believe, been cases of *aneurism of the thoracic aorta*, which, by its pressure on the first divisions of the air-passages, or on the nerves thereabout distributed, had caused that kind of laboured and stridulous breathing which is characteristic of laryngitis. I may venture to say that no person who has had opportunities of educating his ear for the purposes of auscultation, and has made a proper use of those opportunities, could ever overlook such a complication as this. I have myself seen a woman (I mentioned her case before), whose trachea was laid open by a surgeon while she was suffering under mere hysteria; so closely did that disease mimic laryngitis.

When you have good evidence that a meehanical obstruction to the passage of the air exists in the larynx, and that the tubes *beyond the larynx* are pervious and free; there are two things which I would urge upon you. First, I would most earnestly advise you not to *wait too long* before you propose or perform tracheotomy; and secondly, never to omit performing it *merely* because it may appear to be then *too late*. If, in the acute and limited disease, an artificial opening be made while the patient's strength is yet entire, and before his whole system is poisoned with venous blood, or his lungs are overwhelmed with sanguine congestion and serous effusion, it will almost infallibly save his life. But if the sinking of the vital power have got beyond a certain point, tracheotomy will not, in that case, rescue him. It is bad and foolish practice to wait, and try other methods, and postpone the operation as a *last resource*, when the circulation is evidently loaded with unarterialized blood. In my own case I should choose to be operated on early; the moment that I found early blood-letting was not *telling* upon the local distress, and that any shade of duskiness became perceptible in the skin: just as I should choose to be operated on at once for strangulated hernia, after one fair attempt had been made by a skilful hand to return the

bowel; without waiting till inflammation set in, or had been *caused* by the taxis. On the other hand, if you do not see your patient until his powers are nearly exhausted, do not abstain from the operation even though you may feel convinced that it will be unsuccessful; for if it do not save life, it will disarm death of its agony. A patient will lie sometimes for hours, painfully labouring for breath in deep and strong catches, at considerable intervals from each other: in fact, he is just in the condition of a man with a cord round his neck, not pulled quite tight enough to suffocate him at once. Besides, it is not always easy to say whether the period of possible recovery *is* yet gone by. I had a female patient in the hospital who had suffered one or two attacks of frightful dyspnœa, in which the main difficulty was referred to the larynx; but she had rallied from them before any steps could be taken for performing tracheotomy. On the next occasion, however, the seizure was so sudden and rapid, that although Mr. Arnott was luckily in the hospital at the time, the woman was, to all appearance, dead, before he could be found and brought to her bedside. Respiration had entirely ceased. This quietude of the larynx rendered the operation more easy. Mr. Arnott speedily made an opening into the trachea; some air was blown in through the aperture, and then pressed out again; and presently the natural respiration was renewed. The woman recovered; the orifice healed up, and she left the hospital. Three or four months afterwards word was brought that she had died at her own home after a short attack, and when there was no one at hand to open her windpipe. We got permission to examine the body, and found a large ulcer in the trachea, near the larynx; which ulcer by its irritation had occasioned, as we presumed, the spasmodic closure of the glottis. A preparation exhibiting the diseased parts is on the table before you. You see that there was enlargement of the thyreoid gland. This had probably nothing to do with the symptoms. There was also a large ulcer in the left bronchus.

Mr. Goodeve, surgeon to the Clifton Dispensary, operated on a patient in whom "no pulse could be found at the wrist; his face was suffused with blood, and his lips livid; and it was hard to say whether he breathed or not:" yet he recovered.

It so happens that there is at present (December, 1838) under Dr. Wilson's care, in the hospital, a woman named Slack, who was rescued when almost *in articulo mortis*, by the same expedient. She had chronic disease of the larynx; but a sudden aggravation of the symptoms occurred; she became stupid and comatose, her countenance was cadaverous, her skin covered with a cold clammy sweat, and her breathing, which had been stridulous and laryngeal, had almost, if not quite, stopped. She was making short, gasping efforts to respire, not oftener than twice in a minute. Her pulse was intermittent, and extremely feeble. In this conjuncture the house-surgeon (Dr. William Merriman) made a small incision in the skin over the cricoid cartilage, and then thrust a large trocar into the windpipe. Air rushed through the opening, the respiration returned, the pulse revived, and the stupor passed away. This happened on the 10th of October. She is still in the ward; the aperture has closed up: and though she is not well, she is *living*.

What is the reason, you may ask, of these different and inconsistent results? How is it that tracheotomy shall reanimate one patient, whose last breath, but for its help, was already drawn, who was already motionless in apparent death; and yet shall fail to save another patient, who is still alive, and sensible of his danger, and struggling with his disease? The difference depends, I make no doubt, upon the time that elapses between the commencement of extreme dyspnœa, and the performance of the operation: upon the slow or the speedy completion of the strangling process. And this, again, obviously depends upon the manner and degree in which the passage is narrowed. When the obstruction, though considerable, is incomplete, and does not rapidly augment, the respiration continues to be performed, however imperfectly. Meanwhile the brain gets oppressed, the circulation tends to stagnate, and above all, the lungs become gorged with black blood, and clogged up by effusion into their cells and substance. Secondary causes of apnœa are thus established, which do not cease when the primary cause is at length removed, by the unbarring of the main channel for the admission of air. Whereas when the access of the atmosphere is suddenly or soon shut out, the lungs are not thus mortally injured, but remain capable of resuming their functions when they are again supplied with air.

Tracheotomy, then, will be the most likely to succeed, while the patient is still lively and strong: and after that, the chance of success will be worse in those cases in

which the apnoea has been *slow* in its progress, than in those in which it has been *rapid*. I repeat that, in threatening circumstances, the operation should be done *early*; but that it should not be withheld, through despair, at *any* period of the disease.

The effect produced upon the condition of the patient by the timely formation of an artificial glottis, is very striking. The moment that the scalpel penetrates the rings of the trachea, air begins to hiss through the incision; and when a fair opening is established, and a full inspiration is made through the wound, several forcible expirations generally succeed, whereby a considerable quantity of mucus is expelled, which could not pass the contracted aperture of the natural glottis. Then the breathing soon becomes easy, the anxiety and distress are followed by a perfect calm, and usually the exhausted sufferer sinks into a tranquil slumber. This sleep is apt to be from time to time interrupted by the clogging up of the orifice with frothy mucus. It is requisite that some intelligent person should remain by the patient, to assist him in these emergencies, or he may still be throttled, notwithstanding the apparent prosperity of the operation.

When a sufficient hole has been made in the instrument of the voice, below the glottis, the voice of course becomes extinct, or nearly so; and the patient is as unable to utter a cough, as he is to use vocal language. Now this it is of some importance to notice, for he often wants to cough, in order to clear the air-passages of mucus, or of blood, by which they may be embarrassed; and he may be helped to do so, or taught to help himself. First he should draw in a full breath, and then stop the orifice for a moment with his finger, while he makes the expiratory effort. And as the parts within the larynx recover, the patient, by a similar manœuvre, may enable himself to speak aloud.

As actual examples are more interesting and often more instructive than an abstract of results, I will tell you in a summary manner the history of a case of laryngitis, which occurred in one of my hospital patients, in the latter part of the year 1832. He was an old man, about sixty. His name was Kent. He was brought to the hospital bloated with anasæra, which was most conspicuous in his legs and thighs. His breathing was laborious and difficult, and attended with a wheezing noise, audible at some distance. He could not lie down: he had a hard, but not full pulse. The dropsical swelling had come on suddenly five or six days before; and in the outset his face (he said) was so puffed up that he could scarcely see. He had been bled to the amount of a pint and a half, according to his own account, on the previous evening. I had a vein opened immediately, and twenty-four ounces of blood were drawn; and eight ounces more were taken from the chest by cupping. He was thoroughly purged with calomel and senna. The bleeding gave him very little relief, so far as the respiration was concerned; but the next morning the anasæra had totally disappeared. I found him sitting up in bed, breathing with much effort, and with a loud stridulous noise, which accompanied both inspiration and expiration. He referred all his uneasiness to two points; one of these was the larynx, the other the ensiform cartilage. He swallowed with great pain and difficulty; and every attempt to swallow excited a fit of choking cough. There was no morbid appearance visible in the fauces; every part of his chest sounded well on percussion, and the murmur of healthy respiration could everywhere be heard in his lungs, almost drowned, however, in the louder laryngeal noise. As his strength was entire I had him again cupped to twelve ounces, at the back of the neck; and prescribed three grains of calomel every three hours. He also inhaled the steam of hot water.

Upon visiting him again the same evening, I found the dyspnœa increased. Each act of respiration was attended with a loud croupy noise. His countenance was beginning to be anxious and ghastly. He was restless; and his pulse was less firm. Being now firmly convinced that the operation of tracheotomy was the only thing that could save him, and that it could not safely be delayed, I sent to request that Sir Charles Bell would come and perform it. By the time he arrived the restlessness had increased. The patient was shifting perpetually from one side of the bed to the other, as if seeking some new point of support; his face had become pale; and his lips were turning livid. He spoke with sudden, and as it were convulsive efforts; stating earnestly how thankful he should be to have the obstacle to his breathing removed; and pointing to the larynx as the seat of his distress.

The ordinary operation, under such circumstances, is by no means an easy one to perform. Its difficulties were well exemplified in this patient. In the first place he was sitting up; he could not bear to be placed in the recumbent position. Then the dyspnœa caused him instinctively to elevate his shoulders, and sternum, and clavicle, to the utmost, so that the trachea was sunk deeply into the thorax; and the larynx was in constant and rapid movement up and down with a plunging motion, like that of the piston of a steam engine. Sir Charles, after some trouble, succeeded in cutting out a piece of the cartilage: for a mere slit did not suffice: it closed tightly during every inspiration, although it was open enough during expiration. At length, when the air was freely admitted, the breathing became gradually easy. I shall never forget the whole spectacle: there sat the poor man gasping and fighting for breath; his face covered with sweat, and wearing the most anxious expression. By and by what I have called an artificial glottis is opened for him; and presently afterwards, though half a dozen candles (as Sir Charles has himself painted the scene) are held close to his face, to throw light upon the wound, and though the surgeons, their hands smeared with blood, are still busy about his throat, making arrangements to ensure the patency of the orifice, the patient falls fast asleep. It was necessary to place an assistant behind him to prevent his head from nodding forwards, and deranging the apparatus in the wound. Nothing can express more strongly than this fact, the great distress and fatigue which had previously existed, and the perfect relief afforded by the operation.

This man ultimately got quite well: and he has since shown himself occasionally at the hospital, in excellent health. There were two or three points about the case which I am unwilling to pass over without notice. It was evident, after the opening was made in his windpipe, that he still breathed in part through the rima glottidis also; for the stridulous sound did not wholly cease. The aperture was formed as low as the circumstances of the case appeared to permit: the tube was perforated in the membranous space between the thyreoid and the cricoid cartilages. Strictly speaking, *laryngotomy* was the operation performed. I do not enter into the consideration of the best place for making the opening: that point you will be taught by the professor of surgery: but it was observed in the case in question, that the slightest touch of the irritable mucous membrane, with a hook or a probe—especially if the touching instrument were turned *upwards* towards the glottis—produced a fit of coughing, and a paroxysm of still more laborious breathing. For some days after the operation, it was noticed that a part of whatever liquid he swallowed *appeared immediately at the wound*. Now this proved as plainly as if we could have seen the parts, that the epiglottis was thickened, and erected, and incapable of performing its protective function to the larynx: and it accounted for the paroxysm of choking cough produced by each act of deglutition. At first the lining membrane of the larynx and trachea was so irritable, that the patient could not bear to have a metallic tube inserted; and an ingenious contrivance was adopted for keeping the orifice from being covered over by the lips of the wound. They were held apart by two bent wires, which were tied together at the back of his neck. After twenty-four hours had elapsed, the irritability of the nucous membrane had so far abated that he was able to breathe through a canula.

There cannot be a doubt that this man was snatched from the very jaws of death by the intervention of the surgeon. A function indispensable to life was nearly suspended; and a substitute for the faulty organ was provided by art, until the interrupting cause was removed. Scarcely a year passes over our heads without the occurrence of one or two such events in the hospital. When lecturing upon this subject last season, I was able to show you a female patient whose life had been saved in a similar way. And there is now also (December 11, 1839), in Pepys' ward, a rescued man, with the tube still in his windpipe. The operation was done on the spur of necessity by Mr. Tomes, the present house-surgeon, with a trocar. The patient, who was previously in a state of extreme distress, said, in a faint whisper, as soon as the opening was effected, "It's all right now."

He had been exposed to rain and cold about a week before; and had suffered pain and tenderness of the larynx. Prior to his admission he had been bled, and *sali-vated*, and had a *blister on the throat, which embarrassed the operation*.

Within the last eight years the operation of tracheotomy has been performed in

the Middlesex Hospital fourteen times. Seven of the patients recovered; seven died. In two of the seven fatal cases, the condition of the patients was hopeless at the time of the operation. In four at least of the five others much relief from suffering was afforded by it, and life apparently prolonged. One of the patients was a young child; the opening was made by a trocar: much blood got into the air-passages, and the child, which seemed to be sinking previously, died within the hour. Life might, I think, have been preserved in this case, by a *timely* operation, properly done. For a trachea so small, the scalpel is preferable to the trocar. But in the adult subject I have seen the larynx penetrated so neatly, easily, and speedily, both by Mr. Arnott and by Mr. Shaw, with a small curved trocar, that I am persuaded of the general superiority of that method over the common operation with the knife or scissors. If this be granted, the fit place for the opening must be the membranous space between the thyroïd and the cricoid cartilages. The superjacent skin is first nicked with a scalpel: the larynx is then fixed for a moment by the operator's left hand, while with his right he thrusts the instrument steadily inwards and downwards.

I have said nothing hitherto about the use of mercury in this acute disorder, because I hold it to be of very secondary importance, and because I have been anxious not to divert your attention from the two great practical points, *bleeding* and *tracheotomy*. Mercury may very fitly be given in those cases and circumstances in which blood-letting appears proper; but we cannot depend upon it: we cannot reckon upon its influencing the system *in time*; nor upon any marked improvement of the symptoms when it does produce its specific effects. After the operation it is for the most part unnecessary.

Nor do I recommend the employment of tartar emetic, powerful as that drug is known to be in subduing inflammation of the mucous tissues. In the swollen and unpliant state of the epiglottis it would not be prudent to excite, or to hazard, vomiting. The contents of the stomach passing upwards would be apt to enter the unprotected larynx, and to cause hurtful, distressing, and even perilous attacks of suffocative cough.

In the examination of fatal cases, sometimes the thickened membrane forming the edges of the rima glottidis is found covered with viscid mucus, which had formed an additional impediment to the passage of air towards and from the lungs: sometimes pus is discovered, lying in the sacculi laryngis, or scattered among the cartilages and surrounding muscles: and sometimes the chief morbid condition is the infiltration of the submucous areolar tissue. The effect in all cases is the same, that of closing up, wholly or partially, the narrow fissure between the arytenoid cartilages. The state of the epiglottis I have several times described.

This very serious disease is a disease of adult age: it is not often known to occur in children. They again are almost exclusively liable to *croup*: and *cynanche laryngea* has been called the croup of adults. But as the part occupied by croup, and the event of the inflammation, are both different from those of laryngitis, this name, croup of adults, is objectionable. I may remark, however, that sometimes in true croup, the inflammation, besides specially affecting the membrane of the trachea, extends to that of the larynx also.

The main exciting *cause* of laryngitis is exposure to cold, or to cold and wet. My hospital patient, Kent, was a seller of small wares in the streets, and must therefore have been habitually in the way of such causes. The first attack of the disease in Sir J. M. Hayes was brought on by exposure at an open window to the night air for some time, while he was undressed, and in a state of profuse perspiration, with a strong breeze blowing upon him. Dr. Craigie states that young persons from tropical climates, from the West Indies for example, are apt to be attacked by laryngitis soon after their arrival in Europe.

The disease is liable to be produced also by mechanical violence, or chemical injury done to the larynx. It has been caused, on many occasions, in children, by their attempting to swallow boiling water from the spout of a tea-kettle; and life has been saved in such cases by the performance of tracheotomy. The mineral acids, taken as poisons, have excited the disease. Fatal laryngitis has followed the incautious application of ammonia to the nostrils, in cases of hysteria, and of suspended animation: and I once knew a man nearly killed by the inhalation of the fumes evolved from cinnabar thrown upon a hot iron, in what is called *fumigation* of the throat for vene-

real ulceration of that part. I am afraid that I must confess also to have once seen acute laryngitis produced by the bungling attempt of a young surgeon to introduce the stomach pump, in a case of poisoning.

In all these cases the laryngitis is primitive. But laryngeal inflammation, and especially laryngeal *œdema*, not unfrequently take place, and prove suddenly fatal, in the course of other diseases. I have apprised you that in *cynanche tonsillaris*, the inflammation sometimes steals onward to the larynx. I have seen two or three cases of erysipelas of the head, attended, as it almost always is, with sore throat, wherein death took place suddenly and unexpectedly, and where the epiglottis, and the edges of the fissure of the glottis, were found to be *œdematous*: the inflammation of the throat had extended to the areolar tissue beneath the mucous membrane of those parts, and had led to the effusion of serous fluid there. The very same thing is apt to happen in other forms of exanthematous disease attended with sore throat, and especially in small-pox, measles, and scarlet fever. I have known a similar condition of inflammatory *œdema* arise from a *mercurial* sore throat, in a broken-down constitution. In these cases the laryngeal affection is consecutive, and secondary; and in all of them the great remedy is the formation of a sufficient aperture beneath the obstructed glottis. In all of them also the essential symptoms, warranting and demanding the operation of tracheotomy, are the same.

Since the foregoing remarks were delivered and published, this subject has been brought before the profession by Dr. Budd, in a paper read at one of the meetings of the Medical and Chirurgical Society, in 1847. He relates several cases, and refers to others, which justify the belief that acute *œdematous* inflammation of the larynx, is connected more frequently than had hitherto been supposed with erysipelas. That disorder, as I shall hereafter show you, is apt to be propagated from person to person by infection; and the effects of the poison, which thus excites the disease by contaminating the blood, are sometimes displayed first of all in the fauces and their vicinity. Now these effects, redness and thickening of the epiglottis, and of the lips of the glottis, with the effusion of sero-purulent fluid in the submucous areolar tissue—sometimes prove fatal, producing death by apnoea, before the erysipelatous inflammation has time to spread far, or to declare its true character by developing itself upon any part of the external skin.

Fig. 34.

Fig. 35.

Fig. 35.—*œdema* Glottidis.

Fig. 36.

Fig. 36.—Acute *œdema* Glottidis; exposed from behind.

A distinction has been made between *laryngitis* and *œdema of the glottis*; and it is a just and real distinction. *œdema* of the loose areolar tissue subjacent to the mucous membrane of the glottis is indeed one common consequence of inflammation of

that membrane: but it may occur independently of inflammation. The lips of the glottis become tumid and *dropsical*, sometimes (as I have just pointed out) in consequence of a low inflammatory action in the throat, but sometimes also from obstruction of the veins leading from that part. When laryngeal dyspnœa accompanies aneurism of the thoracic aorta, it may, in some instances, result from local dropsy thus produced; and then tracheotomy is fully justifiable, and indeed demanded.

[In a very able paper on œdematous laryngitis, and its treatment, by Dr. Gurdon Buck, of New York, contained in the 1st vol. of the Transactions of the American Medical Association,¹ it is remarked that "the question of diagnosis in this disease is one of vital importance. Without stopping to notice the distinctive symptoms which have been generally regarded as characteristic of this disease, or those of other diseases that are most likely to be mistaken for it, I beg leave to insist upon one sign which is strictly pathognomonic, and does not appear to have been sufficiently appreciated. I refer to the swelling of the epiglottis as ascertained by the touch. The discovery of it, according to Bayle (*Dict. des Scien. Med.*, t. xviii, p. 507), is due to M. Thuillier, who proposed it in a thesis sustained before the Faculty of Medicine in Paris, in 1815. The value of this sign will be admitted if we consider how frequent the swelling of the epiglottis coexists with that of the glottis. Bayle (*loc. cit.*), who dissected more than seventeen cases of this disease, says: 'the epiglottis is rarely intact, often it is very much swollen at its edges.' Ryland says (*Diseases of Larynx and Trachea, Philada. Ed.*, p. 48): 'The œdema is seldom confined to these localities, but extends to the base and lateral edges of the epiglottis.'

"Among seventeen cases collected from different sources, and in which the condition of the epiglottis was ascertained, either by dissection after death, or by the touch or inspection during life, swelling was found in fifteen. Of the eight cases reported in this paper, the epiglottis was found swollen in seven, and in the remaining one there was no evidence that it was not swollen.

"The swelling takes place either at the margin, on one or both sides of the median line, or on the lingual surface of the epiglottis at its base, filling up one or both depressions between it and the tongue, and obliterating the central glosso-epiglottic frænum. It conveys to the touch the sensation of a soft pulpy body, easily recognised and distinguished from the stiff rigid swelling of these parts in membranous laryngitis.

"The facility of ascertaining the condition of the epiglottis with the end of the forefinger, not only by placing it in contact with its anterior surface, but by passing over its upper edge, and applying it upon its posterior surface, has been already noticed. To test this question still further, the experiment has been repeated in at least twelve individuals, and in all with success, though not with equal facility. In some, these parts were easier of access than in others, but in none did the experiment fail. In the exceptional cases, where the epiglottis is not found swollen, the edges of the glottis may be brought more within reach by pressing up the os hyoides with one hand, applied externally over it, and acting from below upwards, while the forefinger of the other hand is introduced as directed into the mouth. Should this not accomplish the object, the fore and middle fingers may be thrust far back into the pharynx, as is required for the removal of a foreign body lodged in the throat."—C.]

The main practical difference between mere œdema glottidis and acute laryngitis, is this: that in the former, there being no fever or inflammation, blood-letting is not requisite: and the operation of tracheotomy becomes almost the sole resource to which, in the extremity of danger, we can look for help. Mere œdema glottidis is seldom attended with dysphagia too, than is laryngitis; yet if the epiglottis be involved in the œdematous swelling, and unable to shut over the glottis, the act of swallowing will be followed by strangling cough, and increased dyspnœa.

Mr. Busk has recommended a peculiar mode of treatment in these cases; whereby he believes the lives of two patients to have been saved, in the Seaman's Hospital on board the Dreadnought. The treatment consisted in making numerous minute punctures

¹ See, also, a further paper by Dr. Buck, on the same subject, in the 4th volume of the Transactions.

tures, with a sharp-pointed bistoury, in the back of the tongue, in the uvula, and in the pharynx. The operation was repeated every half-hour for two or three hours, and the parts were gargled in the interim with warm water. A great discharge of serum took place, and the relief was sudden and decided. Mr. Busk is of opinion that this proceeding would often preclude the necessity of laryngotomy.

[This plan of treatment was first proposed in cases of œdematous laryngitis by M. Lisfrane, but was entirely lost sight of until recently. Dr. G. Buck, of New York, in the paper already referred to, has called attention to the importance of free scarifications of the œdematous edges of the glottis, as well as of the epiglottis, as a means of affording effectual relief from the distress and danger attendant upon the serous infiltration of these parts, and has devised a knife for the more ready performance of such scarifications. For an account of his manner of performing the operation—the difficulties to be encountered in certain cases, and the history of a series of cases in which it was performed by him, we must refer to the papers indicated.—C.]

Besides the affections which I have now described or referred to, the larynx is liable to *chronic* disease: to chronic *inflammation*; chronic *thickening* of the membrane; slow *ulceration*; necrosis of its cartilages. Chronic inflammation and ulceration of that part is very common in *consumptive* patients. It is attended first with hoarseness, then with aphonia, a barking or stridulous cough, and all the melancholy accompaniments of tubercular phthisis. There has accordingly been a species of phthisis spoken of as *phthisis laryngea*. But in most, if not in all cases, this laryngeal affection is only a part of the complaint under which the patient labours; and what I have further to observe respecting it, I shall postpone until we come to the consideration of tubercular consumption.

Again, the membrane lining the laryngeal cartilages is not unfrequently thickened and ulcerated in *secondary syphilis*: giving rise to a hoarse croaking voice, and a noisy and painful breathing. In such cases, or in chronic thickening of the same parts from common inflammation, you may do great good by *gently* introducing mercury into the system, until the gums rise. I have again and again seen the uneasiness about the throat, the noisy respiration, the rough or whispering voice, all cease, as if by enchantment, so soon as the specific influence of the mercury became manifest. There was a woman who used to apply at the Middlesex Hospital for an affection of this kind: whether it was syphilitic or not I could not well determine, but she lost it under the employment of mercury, two or three times: the complaint returning again after the interval of a few months, upon the reapplication of some irritating cause. In another female patient, who was long under my care in the hospital with similar symptoms, everything failed to give permanent relief, till I began to leech the neighbourhood of the larynx repeatedly. She had four leeches applied, I think, every night, and then every other night, for a fortnight or three weeks; the hoarseness and difficulty of respiration gradually diminishing all the time, until at length the perfect use of the instrument of the voice was restored. In these cases, while using local depletion, or mercury, it is often necessary to uphold the strength of the patient by nourishing but unstimulating diet: and it is always expedient that the organ should be kept, as much as possible, in a state of repose.

It is said that a little practice will enable a person to pass his finger into a patient's throat, and to familiarize his sense of touch with the ordinary condition of the upper part of the respiratory apparatus, so as to enable him to detect swelling, or irregularity, or thickening about the chink of the glottis. And great advantage is sometimes obtained from applying remedies directly to the diseased or irritable part. This practice was much followed by the late Mr. Vance, who had been for many years a naval surgeon; and he called it, in naval phrase, *swabbing* the affected organ. A small piece of sponge, secured with a string, or fastened to the end of a finger of a glove, is dipped in a strong solution of nitrate of silver, and then carried down into the throat, as far as that spasmodic state of the muscles which the attempt induces will permit, and pressed downwards against the superior surface of the larynx. I believe other stimulating applications are sometimes employed in place of the nitrate of silver. Now of this method of cure I do not know much, except by report. I have heard that many cases of chronic hoarseness and cough have speedily been

cured by it. But I have more than once had what seemed satisfactory evidence of the beneficial effect of this expedient. The man Kent, whose case I have related, gradually regained the power of easy breathing through the natural passage; and the opening, which Sir Charles Bell had made, closed up perfectly. About a week after this took place, he began again to respire with a wheeze almost as audible as that which existed at the time of his admission: and to speak in a hoarse voice; and a night or two after the return of the wheezing, he had a paroxysm of extreme dyspnoea. I began to be afraid that the whole process of laryngotomy and the metallic tube would be again requisite. However, I got Sir Charles Bell to examine the interior of the throat, and we agreed that it would be advisable to swab the epiglottis and upper part of the air-passages with a strong solution of lunar caustic. For he had no fever, and we thought it probable that the membrane might have been left lax, and in a state to be benefited by astringents. Sir Charles applied the sponge with very little difficulty; and the next day the breathing was greatly improved, and the hoarseness almost gone: and he never had, from that time, any recurrence of troublesome dyspnoea.

Mr. Arnott has on some occasions, at my request, swabbed the upper part of the larynx for intractable hoarseness and aphonia; but with no good, nor any bad consequence.

The lining membrane of the larynx is liable also to warty growths, which impede the entrance and exit of air, and ultimately destroy life. There are several examples of that kind on record. I extract the following from my note book:—

George Tenon la Font, aged 11, admitted March 4, 1828. He speaks in a whisper; complains of difficult breathing, and of cough. Inspires with a loud wheeze. Coughs with a sort of whistling sound, as through a narrow tube. The cough is most troublesome at night. Expectoration mucous, and inconsiderable in quantity.

Has been ill, in this way, all the winter—having had whooping-cough in the preceding autumn. There are marks of eupping on his throat. Little can be heard in the chest, the loud wheeze of his respiration obscuring all other sounds. In about a fortnight his gums were brought under the influence of mercury. No perceptible improvement ensued. A careful examination was again made of the thorax, and the conclusion arrived at was, that the obstacle to his respiration lay in the larynx, or upper part of the trachea, and that the lungs themselves were not concerned. After this, a blister to the throat, a seton near the thyroid cartilage, small doses of ipecacuanha, emetics, and iodine were successively tried—but in vain. Towards the end of the month he began to suffer, occasionally, very violent and apparently spasmodic attacks of extreme dyspnoea. He died, during the night, two months after his admission. For some days before, he had been manifestly worse than usual, was more feeble, wandered somewhat, and complained that his vision was imperfect. No noticeable increase had taken place in the difficulty of breathing, except during the paroxysms of aggravation already mentioned. His death was sudden, and probably took place in one of these paroxysms.

When the body was examined, the lungs were found sound as to structure, but copiously infiltrated, especially on the left side of the thorax, with serous fluid. At the very top of the larynx, involving the base of the epiglottis and the vocal cords, was a considerable warty growth, closing the rima glottidis almost entirely. The excrescences sprang chiefly from one continuous base, and branched out precisely after the manner of what is vulgarly called a seedy wart. There were, however, several distinct smaller growths or warts. The main excrescence, having several heads, passed upwards from and through the rima, and so came to act partly as a valve during inspiration, which was always sensibly more difficult than expiration.

Ought tracheotomy to have been performed in this case? I now think so. But supposing it to have been done, and to have been successful, the boy would have been under the necessity of breathing through an artificial tube for the remainder of his life. A private patient of mine wore such a tube for three years and four months; till he died of consumption.

In the 38th volume of the *Medico-Chirurgical Transactions*, Dr. Barker has recorded a case very closely resembling that which I have just detailed to you.

There are two excellent specimens of warty growths in the larynx, upon the table before you.

I might have referred, when speaking of chronic enlargement of the tonsils, in the last lecture, to the case of a little boy at present under the care of one of my colleagues. He was brought to the hospital on account of great dyspnoea, and a hissing respiration, produced apparently by two enormous tonsils. With some difficulty, (arising from his unmanageable age) a large part of one of the tonsils was cut off with scissors: but after the operation (either from some fresh swelling of the parts, or from pressure made by the remaining tonsil, which grew downwards, I understand, into the throat), his difficulty of breathing became extreme; and it was thought necessary to perform tracheotomy, which afforded him signal relief. He breathed for some time through the artificial opening in his windpipe. At length the other tonsil was partly removed: and the child is now well, and about to be discharged.

LECTURE XLVI.

Cynanche Trachealis; Symptoms; Pathology, Prognosis; Treatment. Diphtheritis. Child-crowing, or spurious croup.

I PROCEED this afternoon to another of Dr. Cullen's species of cynanche; the last that I propose to consider in this part of the course: viz., *cynanche trachealis* — *tracheitis* — *croup*.

The essence of this complaint is violent inflammation, affecting the mucous membrane of that portion of the air passages which lies between the laryngeal cartilages and the primary bronchi: in one word, of the trachea, or *windpipe*. This is the genuine seat of the disease: but the inflammation sometimes ascends into the larynx; and not unfrequently it dives into the bronchi and into their ramifications.

[In perhaps the majority of cases, the inflammation in croup commences in the mucous membrane of the larynx, and from thence extends into the trachea — the disease is therefore, strictly speaking, a *laryngeo-tracheitis*. In many instances, however, we have reason to believe that the inflammation commences in the bronchi, and from thence extends to the trachea; but there are we suspect, very few cases indeed, if any, in which the disease is confined to the trachea. In cases of croup that have terminated rapidly in death, the inflammation and pseudo-membranous exudation which form so striking a feature in this disease are found only in the larynx and upper portion of the trachea — when death occurs at a later period the exudation is often present in the trachea alone, or in the trachea and bronchi; it is never found to exist in the latter tubes alone. It has been attempted to be shown by Jurin and others, that, in the ordinary form of croup, the disease is, in its first stages at least, simply a tracheitis, and that in the more violent and rapid form, (suffocating croup), the inflammation is confined to the larynx. Although this is not strictly true, as is proved by the result of numerous dissections, yet our observations have shown us, that in cases marked by symptoms of great violence, which are sudden in their onset and rapid in their progress, the indications of inflammation are to a much greater extent, and the pseudo-membranous exudation more copious about the larynx, glottis, and upper portion of the trachea, than in cases in which the disease succeeds to bronchitis, runs a more protracted course, and is attended by symptoms of less violence. For a more detailed account of the pathology of croup, the reader is referred to the Editor's Treatise on Diseases of Children. — C.]

Cullen makes no distinction between cynanche trachealis and cynanche laryngea. Yet they are separated from each other by very definite boundaries. They differ in anatomical position: they differ in gravity. Both indeed are serious diseases; but croup is the more serious, because it seldom admits of that mechanical relief which, when rendered in time, deprives cynanche laryngea of its dangerous character. The

two disorders differ also in respect to the period of life at which they occur. Idiopathic laryngitis is seldom met with except in adults; croup seldom after the age of puberty. Cynanche trachealis is indeed a very remarkable disease, for it exhibits an event of inflammation which does not usually belong to that process when it affects the *mucous* tissues. In this too it is unlike laryngitis.

[In a very excellent monograph on *The Pathology of Infantile Laryngo-Tracheitis, or Croup*, Dr. E. R. Peaslee, of New York, has very clearly shown that the idea of the inflammation in croup having a peculiar or specific character is one altogether erroneous. That the disease is simply a laryngo-tracheitis, and as such, stands in intimate relationship to, or rather, is identical with, this form of inflammation, whether it occur in the adult or infant—whether it run its course to a favourable or unfavourable termination, or with or without the production of a false membrane. On this particular point the general conclusions of the author are as follows:—

“1st. An inflammation of the larynx, extending into the trachea, occurs, offering in its essential nature nothing different from any other case of inflammation of the same parts, either in the infant or the adult. It is generally preceded, in both infants and adults, by congestion and irritation, and therefore, by catarrh.

“2d. An exudation of plasma occurs on the inflamed surface, as in the adult; this being most abundant in the trachea on the posterior wall, for reasons already given.

“3d. This exudation may be disposed of, in at least two ways, provided it is not at once removed, as it generally is, in adults but not in infants, by coughing; reabsorption probably very seldom occurring in this disease, though it is not impossible. *a.* It may become degenerated into pus—purulent matter—and thus, of course, at once be detached, which is the most common result. *b.* It may become organized into false membrane. This is more probable if the blood is rich in fibrin, as in a plethoric child; if there is but little cough, an adult generally expelling it thus, and if time is allowed for its development, less being required in the child than the adult.

“4th. Croup is, therefore, merely a laryngo-tracheitis in infants and children, and offers nothing essentially different from the same inflammation in adults. The exudation in the case of adults is, however, usually at once ejected by coughing, or in the form of purulent matter, while the liability to its organization in infants is greater, though, after all, a comparatively rare result, considering the whole number of cases, for the reasons before mentioned.

“5th. Practically, therefore, as well as pathologically, we cannot say with Bouchut, ‘*without a false membrane, croup does not exist.*’ This membrane never exists till the inflammation—the essential element of the disease as we believe—has preceded, and has produced the exudation of plasma, as before shown. No sooner does the catarrhal irritation merge into inflammation, than the plastic lymph is thrown out, and this *inflammation and its accompanying exudation* are the elements always present in croup.

“We, therefore, need not for any practical purpose, admit an ‘inflammatory and membranous’ croup, as some writers have done, any more than we should make the same distinction in regard to pleuritis or peritonitis. All *croup is inflammatory*, at any rate, and a few cases are accompanied by the formation of a false membrane. But the latter should not affect the treatment of the disease as an inflammation, but merely from its mechanical effects, and cannot be predicated in any case till it is actually seen, and this is not possible in most cases in which it is developed at the very onset of the disease. Finally, we would drop the word croup entirely, and use the term *laryngo-tracheitis* instead. In a work on diseases of children, we would call particular attention to the fact that a false membrane is formed in about one-sixth of all the cases of this disease, while in adults, this is of very rare occurrence. But we would not make an accident the distinguishing feature of this disease, any more than we do in the case of others, nor allow it to enter into either our name or our definition of it.

“As in all other inflammations, so in this, the distinction of ‘*sthenic*,’ and ‘*asthenic*’ is important, both in a pathological and a therapeutical point of view. So far, also, as laryngismus enters into any particular case—and it does into all cases of true laryngitis to some extent—the case is, of course, *spasmodic*, but this term must not be applied to the exclusion of the idea of inflammation. *Genuine spasmodic* croup is a mere laryngismus. There is more or less spasm in all cases of bronchitis, and still

more in whooping-cough, in the latter case in the larynx also, so that infantile laryngitis does not present any peculiarity in this respect."

"Diphtherite, or the 'croup of adults,' differs not *pathologically* from infantile laryngo-tracheitis. Generally, however, it is an asthenic form of laryngo-tracheitis, since it usually attacks persons already debilitated by other diseases."—C.]

I say that croup is peculiarly a disease of early life; and, wherefore I know not, it affects more male children than female. The interval that lies between the two periods of *weaning* and *puberty*, is the time during which its visitation is chiefly to be apprehended. Comparatively few cases of it occur during the first year of infantile life. There are more in the second year than in any other. This, in all probability, is connected with the change that ensues in regard to diet, upon the child's being weaned. Dr. Cheyne, whose experience of croup was very extensive, says, the younger children are when weaned, the more liable are they, *cæteris paribus*, to this malady. From the second year onwards the number of children affected with croup gradually decreases. Of ninety-one instances referred to by Jurin, one only was after the tenth year. But it does occasionally happen subsequently to the period of puberty, and up to the twenty-first year; and even later. A girl of nineteen, one of my hospital patients, died of it. Some of the cases recorded of croup in the adult were probably, in reality, cases of laryngitis.

[We have met with the disease most frequently in children, between ten months and five years old. By numerous writers the occurrence of croup previous to the seventh months has been denied; others, however, declare that they have seen it to occur, as a primary disease, repeatedly, at an earlier period. — C.]

It is curious that inflammation should thus, at different epochs of life, fix itself upon limited portions of the same continuous surface, and lead to consequences so diverse. We are unable to give any account of this.

The distinctions are real and usual: yet it should be stated that the inflammatory disease of the parts thus contiguously proximate, are apt to transgress their ordinary bounds, to run the one into the other, and thereby to lose their distinctive characters.

Cynanche trachealis is frequently preceded by a slighter and more diffused affection of the membrane lining the air-passages. The child has what is popularly called a cold; sneezes, coughs, and is *hoarse*. Now with respect to this last symptom, Dr. Cheyne makes the following practical remark. Hoarseness (he says) in very young children, does not usually attend common catarrh. When noticed in a district where croup is not unfrequent, it ought to put the parents or the medical attendant of the child upon their guard; especially as much depends upon the early treatment of the disorder. With these symptoms the child is feverish and fretful, and does not sleep well. In the course of a day or two the signs peculiar to croup begin to show themselves: they are well stated by Cullen, in his definition of the complaint. "*Cynanche, respiratio difficilis, inspiratio strepente, voce raucâ, tussi clangosâ, tumore fere nullo in faucibus apparente, deglutitione parum difficili, cum febre synochâ.*" These are the phenomena that characterize croup. Difficulty of breathing; and sonorous inspiration. The last is often almost enough, of itself, to identify the disease. Hoarseness; a gruff voice; sometimes a total loss of the power of vocal speech. A very peculiar and distinctive cough, to which the epithet "*brassy*" has been justly applied; the noise resembling that which would be occasioned by coughing through a brazen trumpet. This remarkable sound is always easily recognised when it has once been heard. It is a *ringing* cough; and the expiration has a ringing character; and either of these, the cough or expiration, is followed by a loud *crowing* inspiration. Then there is the negative symptom; the absence of any difficulty of swallowing: and with all this, inflammatory fever; a flushed face, a hot skin, a frequent hard pulse, thirst.

However, it is by taking the symptoms collectively, that we judge of the existence of croup, and by the rapid progress of the disease; rather than by any particular or pathognomonic sign. Some of the symptoms may occur, separately, when there is no croup. The brassy or metallic cough, for instance, has been known to accompany some chronic affections of the larynx. Dr. Gregory — the late Edinburgh Professor of Physic — knew a man with a venereal disease of the throat, who coughed so exactly

the cough of croup, that he was admitted into the clinical wards of the infirmary every session for some years, that the students might have the opportunity of *hearing* this peculiar sound. So also the remarkable crowing inspiration may take place, as we shall soon see, without croup.

In the outset, the fever generally runs high; and it is of importance, as respects the diagnosis, to mark the presence or the absence of pyrexia. As the obstruction to the passage of air increases, the blood ceases to be duly arterialized: and then, of course, the skin grows dusky, the pulse feeble and irregular, the extremities cold. The cough, also, as the malady thus goes on from bad to worse, ceases to be loud and clanging, becomes husky, and inaudible at a short distance, and the voice sinks into a whisper; the head is thrown back; the nostrils, in perpetual motion, dilate widely; the face is pale and livid, and sometimes bloated; the pupils often expand. When these indications of sinking have come on, the case usually terminates ill: the bottoms of the feet turn black and hard; drowsiness supervenes; some tossing of the arms perhaps; the breathing becomes gasping and interrupted, and the child dies after an *inspiration*.

In other cases the croupy symptoms make their attack very suddenly. A child shall go to bed apparently well, and in the course of the night have all the worst signs of the disease.

[These will be generally found, however, to be cases of spasmodic laryngitis, and to be unattended with the formation of false membrane in the larynx or trachea.—C.]

And it is observable, that whether the attack be altogether unexpected, or whether it have been preceded by hoarseness, sore throat, and catarrh, it usually comes on *in the night*.

Croup resembles laryngitis in this respect, that it runs its course rapidly: proving fatal sometimes within twenty-four, and often within forty-eight hours. It may, however, continue for five or six days before it terminates, whether death or recovery be the result. Dr. Craigie affirms that it is never protracted beyond the *eleventh* day; the fatal or the favourable issue having always taken place by that time. Life is destroyed, in pure circumscribed tracheitis, by the accumulation in the windpipe of a concrete membrane-like substance, which so frequently attends this disease, and is so peculiar to it, that it is called *the membrane of croup*. In cases of recovery this substance has been expectorated in the form of a nearly perfect tube, representing a cast of the trachea; at other times it is coughed up in flat or tubular fragments. In fatal cases it is found sometimes lying in close contact with the mucous membrane, and sometimes quite detached from it: so that it might have been expelled without much forcing or difficulty, if the child could have sufficiently inflated its lungs, and the requisite muscular power had remained, and spasmodic irritability of the glottis had not opposed.

But, in many instances, this albuminous exudation is not confined to the trachea. It often stretches down to, and enters, the ramifications of the bronchi, and reaches even to their termination in the pulmonary vesicles. Sometimes also it is found clothing the mucous membrane belonging to the laryngeal cartilages. This Dr. Craigie denies. But I show you two specimens in which the false membrane, besides filling the trachea, evidently extends into the larynx. One of these comes from the museum up stairs: the other I have borrowed from the Middlesex Hospital Museum: it is the larynx and trachea of the young woman whom I mentioned just now as having died there of croup, at the age of nineteen. The false membrane reached from the tip of the epiglottis to the bifurcation of the trachea. You see the same thing represented in this excellent plate of Sir R. Carswell's, pictured from nature. Usually the adventitious membrane commences just below the larynx, where it is thin and soft: about the middle of the wind-pipe it is more dense and firm: lower down in the trachea, and in the bronchi, it is generally looser again, pulpy, and broken: it sometimes, I repeat, penetrates to the very air-cells. What are called (absurdly enough) bronchial polypi, branch-like casts of the smaller ramifications of the air-tubes, are then apt to be coughed up. And even when this concrete substance is not formed, we have other evidence, often, of the extension of the inflammation throughout the whole downward course of the membrane.

On the other hand, there are a few cases in which this adventitious membrane is not formed at all; the inner surface of the windpipe is seen to be merely reddened

FIG. 37.

and tumid, and covered with viscid mucus; or perhaps with a shred or two of concrete albumen here and there.

The difficulty of breathing, and the characteristic sounds that accompany it, depend, in part, no doubt, upon spasmodic contractions of the small muscles of the larynx: for remarkable aggravations of the dyspnœa are apt to occur, and to subside again; and these aggravations are sometimes brought on by sudden causes — by the movements of deglutition, for example.

I shall have to recur to this spasmodic constriction of the glottis; but I may here remark, that because it has not been (and cannot be) *seen*, doubts have been expressed by some about its having anything to do with the dyspnœa. Such doubts seem scarcely reasonable. It is easy, at any time, by an effort of the will, to close the glottis, and to prevent the passage of air to and from the lungs. This is mainly effected by the action of the little muscles that bring together the arytenoid cartilages. But those muscles, like the other muscles concerned in respiration, act also independently of the will, spasmodically therefore, through the reflex function of the spinal cord. And it is by a providential and conservative appointment that they do so act, as janitors, admitting, in the healthy state, the vivifying air, but barring the door against certain hurtful gases, and against solids and liquids which would be injurious to the respiratory apparatus. We know that if a drop of water, or a crumb of bread, or a whiff of carbonic acid gas, gets past the outer defence, the epiglottis, and into the larynx, spasmodic action of the little muscles in question is instantly excited. We cannot see these intruders, and voluntarily resist their entrance, but the unsleeping sentinel is there to guard the passage. We may well conceive, therefore (and I know

not how the supposition can be disproved), that the noisy and difficult respiration of croup may be caused, in part, by spasm.

[As further evidence of the correctness of this remark may be adduced those cases in which all the diagnostic symptoms of croup are suddenly induced by an irritation seated in the stomach, as from indigestible food, &c., and are as suddenly removed the moment the cause of irritation is expelled. A medical friend has informed us, that in one of his own children, symptoms resembling croup are produced by eating fish, and are immediately removed upon the operation of an emetic. — C.]

The presence of the adventitious tubular membrane in the trachea affords a plausible explanation of one of the symptoms observed in these little patients; the tendency they show to throw the head back. The cylinder of membrane is kept open in that position; whereas, if the head were inclined at all towards the chest, the membrane would be bent upon itself, and the passage through it obstructed.

This concrete exudation is often adduced to prove that the mucous membranes may exhibit, under certain circumstances, the phenomena of adhesive inflammation. Similar films sometimes form upon, or are thrown off by, the mucous surfaces of the intestines, and of the uterus. Whether they are to be regarded as essentially identical with the layers of coagulable lymph poured forth in inflammation of the serous and areolar tissues, may be made a question. There are certainly some strong points of distinction between them. The concrete membrane of croup is more brittle, less fibrous, more decidedly albuminous, than the false membranes that cover the inflamed pleura, pericardium, or peritoneum. A still more remarkable difference is this, that it is not *plastic*, in the sense in which that term was formerly explained; it never becomes organized, never connects itself by blood-vessels with the surface from which it proceeds. On the contrary, it is partially detached; and by degrees, if the patient live long enough, it is completely separated from the adjacent parts.

Hypotheses have been framed to account for the limitation of this product of tracheal inflammation to the early periods of life; and for its variation from the usual products of inflammation of the same part. Dr. Stokes thinks that the predominance of the white tissues in young subjects may explain the greater frequency of croup, with its peculiar membrane, in infants. Dr. C. B. Williams starts the very reasonable supposition that the inflammation involves the submucous areolar tissue, which is abundant during youth; and that the natural product of this phlegmonous inflammation transudes readily through the thin, simple, and delicate mucous membrane proper to that age.

The formation of this adventitious membrane, and even its renewal, appears to be sometimes very rapid. I have here a preparation made by the late Dr. Sweatman, illustrative of this. It now belongs to the Middlesex Hospital Museum. Upon a child on the very brink of suffocation from croup, the operation of tracheotomy was performed, at one o'clock in the morning, by Mr. Chevalier. A tubular portion of membrane, of the shape and size of the trachea, was presently forced through the artificial opening. Immediately, the child's respiration became easy, and it fell asleep. In the course of the same morning, Dr. Sweatman was hastily summoned, and arriving at eight o'clock, found the child dead. It had slept six hours, and upwards; and then the distress of the breathing had returned, and was soon fatal. The trachea was found to contain a new tube of lymph, or of concrete albumen. The preparation shows that such a membrane may re-form in that short space of time; namely, in from six to seven hours.

The croup is not contagious; although, like cynanche tonsillaris, and for the same reasons, it is found sometimes existing at the same time, or in quick succession, in more than one child of the same family. Thus two twin children of Dr. Gregory's were seized with croup on the same night. They had both been walking in the evening on the sea-shore during a cold wind. This is in accordance with what Dr. Cheyne has stated, that the attack is almost always nocturnal, and often when the child has during the preceding day been exposed to the weather. It frequently occurs sporadically; but there are places in which the disease appears to be endemic. Dr. Cheyne found it so on the coast of the Frith of Forth. Indeed, the first distinct account of it that we possess was drawn up by Dr. Home, of Edinburgh, in 1765,

from much personal observation of its ravages in Leith and Musselburgh. Cold situations—and damp places, more than such as are merely cold,—are subject to the prevalence of this disease. It is accordingly frequent in the seasons of winter and spring. It is said to be most common near the sea-shore, and in the neighbourhood of large bodies of water generally. It occurs in low, moist, what are called in Scotland *carse* districts, oftener than in upland situations that are more exposed to cold winds. It is more common at Leith than it is in Edinburgh; and in Edinburgh, it is most frequent in the lowest parts of the town. This I learned from Dr. Alison, who, having long been physician to a dispensary there, had had ample means of observing the disease. Canal Street and the Cowgate, both low spots, as some of you may know, have long been famous, or rather infamous, for cases of croup. Towns situated on the banks of rivers have more than the average share of it; and it has been observed to be particularly frequent among the children of washerwomen in such places; and thus evidently connected with exposure to moisture. In towns so situated, it has been known to prevail epidemically after an inundation.

[Of the frequent prevalence of croup as an epidemic, Berge, Canstatt, Fleury, Val-leix, Wunderlich, and others, furnish incontestible evidence. An epidemic of the disease is recorded as having extended over the greater portion of Central Europe during the period between 1805 and 1807, and one of more circumscribed limits by Terrand in his Thesis on Membranous Angina, published in 1827, during which, in a district of very small extent, there occurred no less than sixty cases of croup, all terminating fatally.—C.]

Dr. Allison has made a very curious remark respecting croup. He says that it seems to be often produced by the child's sitting, or sleeping, in a room newly washed: and that he has noticed its frequent occurrence on a Saturday night—the only day in the week on which it is customary for the lower orders in Edinburgh to wash their houses.

[The remarks in the foregoing paragraph are applicable rather to spasmodic laryngitis than to cases in which there is a formation of false membrane.—C.]

Like cynanche tonsillaris, and unlike cynanche parotidæa, the croup is exceedingly apt to recur. Relapses may happen within a few days after apparent recovery; and these are very perilous. But besides this tendency to a renewal of the severer symptoms, the little patients are often affected with cough, and hoarseness, and even with aphonia, for a long time. And while these relics of the acute attack continue, it is easily brought back again. The first seizure is generally, I believe, the worst: but to this rule there are numerous exceptions.

Croup is a disorder which justly excites extreme alarm in the friends and parents of the patient: for the prognosis can never be better than doubtful. It is said that four children out of five attacked by it used to die: but that now, the treatment being better understood than formerly, the number of deaths and the number of recoveries are nearly equal. We judge of the probable issue, in a given case, by the apparent circumstances and progress of the malady. If we could see the interior of the air-tubes, we should know that the chance of escape was small, in proportion as the inflammation, and its albuminous product, descended along the ramifications of the bronchi. But in these little patients, and amid the tracheal noises, it is difficult to ascertain the physical state of the lungs. The prognosis is chiefly to be collected from the general condition of the child. If the distress of breathing seem to remit, and free expectoration to come on, while the strength is yet entire, we venture to hope. On the other hand, we begin to despair when the lips are becoming blue, the skin is losing its heat, the pulse is already feeble and intermitting, and the little patient is drowsy or comatose: in other words, when we perceive the final symptoms of death in the way of apnœa. Some few patients die suddenly and unexpectedly without any previous coma.

The mortality will differ according as the disease is detected early, and treated vigorously,—or otherwise. And with respect to treatment, there is no specific remedy for this, any more than for any other inflammation. We must put in force the general

principles upon which the treatment of inflammation is founded ; adapting them, however, to the malady in question by those particular rules which the experience of the best observers has collected for our guidance.

I need scarcely say that when cough and catarrh, and especially hoarseness or loss of voice, are noticed in a young child, he should be narrowly watched, and protected against all circumstances likely to excite or to aggravate inflammation : he should be kept in the house, and put upon farinaceous diet ; and the functions of the bowels and of the skin should be attended to.

The three remedies that most require consideration are blood-letting, tartarized antimony, and calomel.

Bleeding is to be unhesitatingly employed when the patient is strong, and plethoric, and seen in the outset of the disease. In judging of its mode, and of its amount, we must recollect that what is no more than a topical bleeding for an adult, becomes equivalent, in its effects upon the system, to general bleeding, when it is used for a very young child. Abstraction of blood by venæsection or cupping in the case of older children, and by leeches in the case of infants, should be practised whenever the symptoms are violent, and there is much fever, and the patient is seen within a few hours after the commencement of the symptoms. The relief that is given by this measure, under such circumstances, is often so decided, that no doubt can remain of its usefulness and propriety.

It is impossible to lay down any fixed rules for the quantity of blood that should be taken in this complaint. Under two years of age, it should not, says Dr. Cheyne, exceed five ounces. I should esteem that a *large* bleeding, at that age. Upon an average, a moderate bleeding will be produced by the application of a couple of leeches to an infant in its first year : and an additional leech may be employed for every additional year : so that six may be put to a child five years old, or eight if he be stout. Dr. Copland estimates the amount of blood which these patients may, with safety, bear, to be somewhat more than an ounce, or as much as an ounce and a half, for every year of their age. Much, however, must depend upon the special circumstances of the case : the quantity of blood extracted by a given number of leeches is less in one instance than in another ; and then, of course, the number must be increased. I have been in the habit of recommending that they should be applied at the upper part of the sternum, rather than in front of the windpipe itself : for this reason :—that the pressure which may be necessary to stop the bleeding, or to regulate its quantity, cannot well be borne upon the throat in these cases. Yet if the process be conducted by the practitioner himself, and not left (as sometimes it inevitably must be) to the casual attendants of the sick child, this incidental difficulty may by care be obviated—and then it will be desirable, as Dr. West suggests, that the leeches should draw the blood from the nearest vicinity of the affected membrane.

After one sufficient evacuation of blood, whether by means of the lancet, or of leeches, or of cupping-glasses applied between the shoulders, it will always be right, before repeating it, to ascertain the effects of other measures ; such as emetics and purgatives, the beneficial operation of which in this disorder is often very remarkable.

Full vomiting sometimes affords relief so sudden and complete, as to lead to the persuasion that the symptoms had been principally owing to spasm. And even when the disease is unequivocally inflammation—sometimes even late, but particularly in the early part of its course—the effect of a vomit is often very striking. It promotes expectoration ; and is not unfrequently followed by the expulsion of shreds of the adventitious membrane. When blood-letting is employed, it should precede the emetic ; or, at any rate, it should precede the act of vomiting. Dr. Cheyne recommends that the bleeding should be practised ten minutes after the emetic has been swallowed. The loss of blood assists the operation of the emetic, and lessens the risk (which is not a fanciful one) of injurious congestion of the vessels of the head during the straining efforts of vomiting.

It is better, in Dr. West's opinion, to re-excite from time to time, as circumstances may require, the act of vomiting, than to aim at prolonging a state of nausea and faintness, which might mask the progress of the disorder towards a fatal ending. In corroboration of the result of his own experience, as to the superiority of emetic over

nauseating doses of medicine, he quotes that of M. Valleix, who states, that in thirty-one out of fifty-three cases of true croup, ipecacuan and antimony were employed in full doses, and fifteen of the patients recovered; whereas, of the remaining twenty-two, in whose treatment these drugs were but sparingly resorted to, all died but one. Now the substance best adapted to our purpose is the tartarized antimony. This medicine, as I have often mentioned before, has great power over inflammation of the mucous tissues: and there is one very great advantage belonging to it in cases of croup; namely, that children may be induced to take it without their knowing that they are taking medicine; for the solution of it has little or no taste: whereas the struggling which is often occasioned by the administration of other emetics may be the cause of much inconvenience, and even of much injury, to the patient. It should be dissolved in boiling water, in the proportion of a grain to an ounce; and the cold solution given. A tea or a dessert spoonful may be repeated every quarter of an hour, till some effect is produced.

[By the majority of physicians the tartarized antimony is preferred as an emetic in croup. Some, however, ascribe a peculiar efficacy to the sulphate of copper, while others again prefer the sulphate of zinc. Many of the American practitioners esteem the *Sanguinaria Canadensis*, in infusion, as almost a specific, while a few prefer the *Lobelia Inflata*. Dr. Meigs considers alum in powder, from the speediness of its operation, to form the best emetic in cases of croup, while Dr. Hubbard, of Maine, recommends the turpeth mineral—the yellow sulphate of mercury—as an emetic in this disease, in consequence of its promptness and certainty, and its never producing catharsis, or being followed by the prostration caused by tartar emetic.]

It is upon these latter considerations that the sulphate of copper has been considered the article best adapted to produce emesis in croup. By many of the continental physicians it is held to be superior to all others. It is recommended by Berignier and Trousseau, in two or three grain doses, but by the latter in doses of five grains, to be repeated after a short interval, should the first fail to produce vomiting.

Dr. Hornerkopff, in a paper published in 1855 (*Journ. der Kinderkrankheiten*), states that he had employed the sulphate of copper in 99 cases of croup, of which 77 recovered. He gave the salt in solution, 6 to 8 grains to one ounce of water, of this from a tea to a table spoonful was given, more or less frequently, according to the age of the patient and the extent of emesis produced. He continues the use of the remedy so as to keep up vomiting or decided nausea until convalescence has been fully established. Dr. J. Sumter, of Posen (*Günsburg Zeitschrift*, 1855), has employed the sulphate of copper very much in the manner recommended by Dr. Hornerkopff, and speaks of it in equally favourable terms.

Dr. Luzinsky (*Schmidt's Jahrbuch*, 1855) gives a decided preference to sulphate of copper in croup. He gives it in solution (two to four or more grains in two and a half ounces of fluid), of which the dose is a tea spoonful every fifteen minutes.—C.]

When vomiting is thus excited on the very first appearance of the symptoms, and before the disease seems thoroughly formed, it sometimes puts it off; so that no other treatment remains necessary beyond the exhibition of some purgative medicine. But when this perfect relief does not ensue upon the operation of the emetic, Dr. Cheyne advises (and this is in conformity with the practice of many other persons) that a powder, consisting of two, three, or four grains of calomel, with two or three grains of James's powder, should be given at short intervals; every two or three hours for example. A dose of castor-oil is to be administered occasionally, to clear the bowels. And another expedient, of great efficacy sometimes, and therefore never to be omitted, is the warm bath. This is often properly resorted to just after the act of vomiting, particularly if any tendency to perspiration be apparent. The temperature of the water should not be lower than 98° Fahrenheit; and the child should remain in the bath for ten minutes at least. When taken out, he should be wiped dry, and put immediately into bed again. The change for the better produced by the bath is sometimes so marked and so speedy, as to strengthen the conclusion that the most distressing of the symptoms had resulted from spasm.

The usual effect of calomel thus frequently repeated is that of causing (not, as in

adults, salivation, but) the discharge of a quantity of green fæcal matter, resembling chopped spinach: and when stools of this kind begin to make their appearance, there is often a sensible mitigation of the symptoms. The green colour is a common consequence of mercury given to young children; and will occur, I believe, whatever be the disease, when the full effect of calomel as a purgative is obtained. The green matter has been found, after death, in all the intestines, small as well as large, up to the duodenum. I presume that the colour is owing to some chemical action that takes place between the calomel and the bile. We know that calomel does tinge bile green when mixed with it out of the body. It may be, however, that the calomel provokes a flow of altered bile.

Calomel thus administered, is the purgative that has received the strongest recommendations. Its usefulness appears to have been fully borne out by the test of experience: and the well-known virtue belonging to mercury, of preventing or arresting the effusion of coagulable lymph in other textures, has formed (I conceive) one cogent reason for its adoption in this disorder, of which the chief peril results from the pouring forth of the albuminous part of the blood. But whether mercury really has the same power of controlling adhesive inflammation, when that process is set up in mucous tissues, which are so commonly exempt from it, may be questioned. On the other hand, the effect of full doses of tartar emetic in restraining active inflammation of those tissues is well ascertained. The act of vomiting helps greatly, also, to dislodge from the air-passages, the phlegm and false membranes by which they are obstructed. For these reasons, the remedy is admirably adapted to the early stages of this dangerous malady. The system can be brought to feel its decided influence with much more certainty, and in a much shorter space of time, than that of calomel: and if it fail to make a beneficial impression, it need not long interfere with the mercurial treatment. Let me quote to you the statement of Dr. Cheyne (whose experience of this disease was far ampler than mine has been) respecting the efficacy of tartarized antimony in what he calls the second stage of croup. He recommends that half a grain, dissolved in a table spoonful of water, should be given to a child two or three years old, every half hour, till sickness and vomiting ensue. In two hours after the last effort of vomiting, the same process is to be recommenced; and so repeated while the symptoms require it, and the strength will permit. This mode of treatment was suggested to him by the accidental observation of a particular case, in which it was remarkably successful. From that time he placed his whole reliance on that remedy in the second stage of croup; especially as he had found that blood-letting in that stage only accelerated the death of the patient. He noticed that the cases were *few* in which he had known children survive the second stage, but in *all* of these few, they recovered while using a solution of tartarized antimony. He held that no other medicine was, at that stage of the disorder, entitled to confidence. In short, he declared "that tartar emetic so given as to produce continued nausea, had been his sheet anchor, in the treatment of croup, since the year 1799." This was written in 1801, in a separate work on the pathology of the larynx and bronchi; and Dr. Cheyne recently has affirmed, in the *Cyclopædia of Practical Medicine*, that he still found reason to adhere to the same opinions, and the same practice.

[Dr. Watson makes no mention of the application of nitrate of silver locally to the throat, in cases of croup, and yet the evidence in its favor is of the strongest character. The best means of effecting this application is by wetting a small piece of fine sponge, firmly attached to the end of a portion of whale-bone, properly curved, with a solution of the nitrate of silver in water, and carrying it to the larynx and on the glottis, and then quickly withdrawing it. — C.]

Now, what is good for the second stage, would, *à fortiori*, I think, be likely to save life, if employed during the earlier stage of the disease. I therefore should say, take blood in the very outset, as largely as may seem prudent: then give the tartar emetic solution in the way already described. As soon as it causes vomiting, and pallor, and a sinking of the pulse, stop: and suffer the heart to recover itself. And if, with the rallying circulation, the difficulty of breathing return, have recourse again to the same remedy. The faintness and collapse are sometimes so great as to threaten the extinction of life: the child, with a flying pulse, and a clay-cold surface, seems

gasping its last. When this happens, a few drops of sal volatile, or of brandy, mixed with water, will presently bring the little patient round again. If no ground be gained after two or three repetitions of the emetic treatment, then it may be well to make trial of the calomel plan.

Sometimes the antimony acts severely on the bowels: it may occasionally therefore be necessary to combine with it a small quantity of syrup of poppies, or of laudanum.

[We have been in the habit, for many years, of prescribing immediately after bleeding in those cases in which this was demanded, and when such was not the case, as our first prescription, a combination of one or two, or three grains of calomel, an eighth of a grain of tartar emetic, and from three to five grains of muriate of ammonia, every one, two, or three hours, according to the urgency of the symptoms present, and the age and vigour of the patient, and we have had much cause to be pleased with the effects of this combination. Under its use all the prominent symptoms often disappear with great promptness. — C.]

Blisters are often applied in this disease; but with very questionable propriety. In the outset they are likely to do harm; in the advanced periods they are not likely to do good. If used at all, they should be placed, not on the throat, but across the upper part of the sternum.

[We do not approve of the use of blisters in this disease. If applied, they should only be kept on for a few hours, so as merely to redden the skin. A much better application is a strip of flannel wet with spirits of turpentine, kept on for only a few minutes at a time, and repeated if considered necessary. — C.]

When signs of approaching death have come on—lividity of the lips, coldness of the skin, and a tendency to stupor—the question *will* obtrude itself, whether there may not still be a chance of saving the patient by performing tracheotomy. In the first place you will consider that the operation is much more difficult to execute upon children than upon adults; and is attended with more perplexing hæmorrhage. But there is a greater objection than this to tracheotomy in such cases—an objection which you will have anticipated—namely, the existence of the preternatural membrane; which often extends so far down, that air would not be admitted into the lungs, even if an aperture in the windpipe were made at the lowest possible point. Another consideration, forbidding much hope of success from this expedient at any period of the disease, is that the ramifications of the bronchi and the ultimate air-cells get filled up with serous, or mucous, or puriform matter, or even sometimes with a membranous exudation, whereby suffocation is effected *in the lungs themselves*. The membrane in the trachea, being tubular, does not entirely exclude the air from those organs; but it does not admit it in sufficient quantity. Tracheotomy has been many times practised in this complaint, and with just enough of success to warrant its repetition in cases otherwise hopeless. Two instances in which life was saved by its performance are recorded in the *Medico-Chirurgical Transactions*: the one achieved by Mr. André, and related by Dr. Farre, in the third volume: and the other by Mr. Chevalier, in the sixth volume. These were both apparently desperate cases. Immediate relief followed the operation in both, and the patients recovered perfectly. More recently five examples of tracheotomy in croup, performed in St. George's Hospital, have been brought before the society by Dr. Fuller. In two of these the operation succeeded; in three it failed.

There seem to be just two predicaments in which there is a fair chance that tracheotomy may be useful. They are perhaps rare: yet they have been noticed by several observers. The one is where the preternatural membrane extends but a very little way down the trachea, and is chiefly confined to the larynx: and the other is where there is no preternatural membrane at all, or only a very slight coating in some part of the trachea, the impediment to the breathing having arisen mainly from the thickening of the mucous membrane. And you will observe that an impediment from this cause will always be the greatest at the narrowest part of the canal: and therefore incision of the windpipe in such a case may be expected to bring relief. The effect produced by the tracheotomy in Mr. Chevalier's case was very instructive. Air was

fully inspired through the opening, then a strong cough took place, by which a large quantity of viscid reddish mucus was forced out by the natural channel, through the glottis. It was evident that the child could not expectorate before, simply because it could not sufficiently fill its lungs with air to drive the collected mucus out. Dr. Farre gives a circumstantial account of a case in which the adventitious membrane did not reach more than a finger's breadth below the cricoid cartilage; and the rest of the tube was so free that he was convinced the child's life might have been saved by a timely opening into the trachea. Unfortunately we cannot tell, before death, to what degree or extent the preternatural membrane exists. All that can be said, I think, is, that when dyspnœa and much croup come on suddenly or quickly, the disease is probably limited to the larynx and upper part of the windpipe: but that when the progress of the disorder is slower, and the croupy symptoms are not so well marked, it is more likely that a greater extent of the trachea, below the larynx, participates in the mischief. Our expectations of success from tracheotomy will vary accordingly. It affords a bad chance at the best; but it affords also, in many cases, the *only* chance. For some sound practical suggestions in regard to the proper management of the operation, and to the after treatment which is essential to its prospering, I must refer you to Dr. Fuller's paper.

[The subject of tracheotomy in croup is one of considerable interest. That in many cases it may, when timely performed, save the life of the patient, we have the most unquestionable evidence. In a statement by M. Trousseau of the result of the operation, as performed by himself, and by others, according to his method, in *one hundred and fifty* cases, the patients were saved in *thirty-nine*. In the case of his own child, three weeks old, recently published by Dr. Scoutetten, the operation was performed on the third day of the disease, under circumstances apparently the most desperate, with complete success—the infant recovering in a short time from the effects of the operation, as well as from every symptom of the croup. The class of cases, the period and particular circumstances of the disease in which the operation is most likely to afford relief, are questions of no little importance, and it is probable that much of the want of success, which many practitioners have experienced in performing the operation, is to be attributed to its having been resorted to under improper circumstances. M. Trousseau, whose experience on this subject has been somewhat extensive, presents the following as a summary of the prognosis of tracheotomy in croup:—

"1st. If the commencement of the attack dates several days back, if, consequently, the disease has advanced slowly, whatever may be the extent of the false membranes in the trachea and bronchi, the children either recover, or live at least several days after the operation.

"2d. But if the disease has been very rapid, even although at the time of the operation we ascertain that the false membranes do not extend beyond the larynx, the children die very quickly.

"3d. If previous to the operation, the false membranes have extended to the nares, or if they cover the blistered surfaces; if the child is pale and somewhat bloated, without having taken mercury or been bled, or if he has lost much blood, there is little chance of the operation succeeding.

"4th. If previous to the operation the pulse is moderately frequent, and if, after it, the pulse remains calm, hopes may be entertained.

"5th. It is a bad sign, if, immediately after the operation, the respiration becomes very frequent, without any cough or with very little.

"6th. More boys than girls are cured.

"7th. Children under two, and over six years of age, rarely recover.

"8th. The more deeply the false membranes have extended, the greater, *cæteris paribus*, the danger.

"9th. If the child has been subject to chronic catarrhs, and if he had been suffering from a cold for some time when he was attacked with the croup, tracheotomy is more successful.

"10th. Even when all is going on favourably, very great frequency of respiration is a bad sign.

"11th. The more rapid and energetic the inflammation which attacks the wound

in the trachea, the better are the chances of success—a sudden sinking of the wound is a mortal sign.

"12th. So long as the respiration is silent or the noise is only occasioned by the displacement of mucus, there is nothing to fear; but when the respiration becomes saw-like (*serratique*), in other words, when it is attended with a sound like that produced by a saw cutting stone, death is certain.

"13th. There is no reason to despair of the patient, even if a pneumonic or pleuritic attack should supervene.

"14th. Agitation and sleeplessness are bad signs.

"15th. Should the wound become covered with false membranes; if, after withdrawing the canula, it remains gaping for a long time, or, if after having become entirely cicatrized it reopens largely, the child is in danger.

"16th. The sooner after the operation the larynx is disembarassed, the sooner may we remove the canula, and the more rapid and certain is the cure.

"17th. If the croup supervened upon rubeola, scarlatina, variola or pertussis, although there is not ordinarily any connection between the malignant angina and these pyrexia, tracheotomy does not succeed.

"18th. If the expectoration becomes mucous and catarrhal by the third day after the operation, the children will recover. If there is no expectoration, or it is serous, or like half-dried portions of gum Arabic, they will die.

"19th. If the patients react vigorously under the injections into the trachea of water or nitrate of silver, and under the sponging out of the trachea, we should not despair, however unfavourable may be the other signs.

"20th. Children attacked with convulsions after the operation die, and the younger the patients and the more blood they have lost before or during the operation, the more often convulsions supervene.

"21st. When, after the tenth day, the drinks pass almost entirely from the pharynx into the larynx and trachea, even if they are readily rejected, the children most generally die.

"22d. The increase of the fever after the fourth day, agitation, sinking of the wound, and dryness of the trachea, frequency of the respiratory movements, and attempts to cough, announce the invasion of pneumonia, which, at first lobular, becomes sometimes pseudo-lobular, and is to be treated by the same means as are usually employed in the pneumonia of children; we should, however, exclude blisters, because they too often become covered with false membranes." (See *Rilliet and Barthéz, Traité des Mal. des Enfants*, t. i., 365-7. — C.]

A severe inflammatory disorder of the throat, much more common in some parts of France than it is in this country, and named by M. Bretonneau, of Tours, who first fully described it, *diphtheritis*—is regarded by Dr. West as a variety of croup. Some analogy with that disease it certainly has; but the points of difference are stronger and more essential. It resembles croup, inasmuch as it leads to the production of an adventitious membrane upon a mucous surface. It differs in the position of that membrane, which is seldom formed in the trachea. The affection of the windpipe, when it occurs at all, is secondary: so that the term cynanche trachealis would be quite inappropriate. The parts first and chiefly concerned are the fauces. A whitish or ash-coloured membrane forms upon the pharynx and tonsils, and extends forwards to the soft palate, and into the nostrils, and backwards into the œsophagus, sometimes into the larynx, but seldom into the trachea. Around it, between its fissures, and in spots from which it has been detached, the mucous membrane is seen to be of a deep red, and sometimes of a purplish or claret colour. The submaxillary and cervical glands are liable to swell, the neck in front becomes full and œdematous, and an acrid discharge from the nose is commonly present.

This very formidable complaint, of which I have not seen more than two or three examples, proves fatal generally by the extension of the inflammation into the air passages. It is attended by fever, commonly of a low type. In Picardy and Touraine it would seem to be endemic; occurring sometimes sporadically, sometimes with an epidemic prevalence, and not without suspicion of contagious properties. In 1855 and 1856 it was rife and deadly in Boulogne. Dr. West has met with the disorder occasionally as an idiopathic affection, but much more frequently as "a most dan-

gerous complication of some other disease, almost always of measles." It seldom begins until the eruption of measles is on the decline, or the process of desquamation has commenced. There is generally so great a depression of the vital powers, as to contra-indicate the employment of active antiphlogistic treatment. The two remedial measures upon which Dr. West mainly relies, are the careful and repeated sponging of the fauces with a strong solution of lunar caustic, (a scruple to the ounce of distilled water,) and the exhibition of tartar emetic in the same manner as in cynanche trachealis. Mercury, by the mouth if the state of the bowels permit, or by inunction—and an early support by nourishing broths and by bark, or wine—form also important parts of the treatment.

The comparative freedom of the windpipe would encourage a trial of tracheotomy in these cases, when life seemed in jeopardy from impeded respiration; but the morbid condition of the blood, and the resulting character of the attendant fever, forbid the hope of such success from that mechanical remedy as it might otherwise promise.

This disease has recently (November, 1855) proved fatal in the family of an esteemed member of the council of this College. The patient, a young man about 17 years of age, was carried off after less than four days of illness. His symptoms, as described to me by my friend Dr. Burrows, were precisely such as I just now enumerated. The respiration became at last laborious, and tracheotomy was performed by Mr. Stanley—but in vain. In the larynx and trachea there was no trace of that sort of coriaceous membrane which covered the tonsils, velum palati, and fauces generally. I mention the case for the purpose of recording that, besides and beyond the usual appearances already specified, the centre of the swollen left tonsil was occupied by a sloughy abscess, while the right contained about a drachm of genuine pus. At no time during the progress of the disorder was any kind of lowering treatment admissible.

[Dr. Willige states (*Schmidt's Jahrbücher*, 1847,) that he has derived marked success in the treatment of severe cases of croup by the external application of iodine to the upper part of the neck. He applied, by means of a feather, the tincture of iodine over the front part of the neck, corresponding to the region of the larynx and trachea, and repeated the application at intervals of about four hours, until redness and irritation of the skin are produced. This, he declares, was followed in most cases by a subsidence of the difficulty of respiration, of the spasmodic affection of the glottis, and of the other distressing symptoms.

The internal use of the iodide of potassium has been suggested as a means, in the first stage of croup, adapted to modify the disposition to membraniform deposition in the larynx. It was first used in a case of the disease by Dr. J. D. Griseom, of this city, with apparently the most favourable results; it has since been employed by others, who speak of it in terms that should encourage us to a trial of it, that its true value as an antiplastic in this disease may be ascertained.

As a means of reducing the plasticity of the blood, and thus diminishing the tendency to the formation of false membrane in croup, the vegetable alkalies have been strongly recommended by several of the continental physicians. Eggert considers the carbonate of potass, after an experience of its effects in about two hundred and fifty cases, as almost a specific in croup; and Luzinsky speaks of it in the most favourable terms, (*Schmidt's Jahrbücher*, 1855). The latter states that it may be given advantageously in doses of from half a drachm to two drachms, daily. In mild cases the carbonate of soda may be employed, but in the more severe, the carbonate of potass is alone to be relied on. — C.]

There is a sort of bastard croup, with which it is quite necessary that you should be acquainted, for it is not at all uncommon; nay, it is far more common, in this place at least, than the real disease. It has received a variety of names, which shows that it has been recognised, as a distinct malady, by various observers. Yet no doubt can be entertained that it has very often indeed been confounded,—and is still continually confounded,—with the true croup, with cynanche trachealis. In their most obvious symptoms the two affections are much alike. The broad and essential distinction between them, is the absence, in the spurious disorder, of inflammation and of fever—and consequently of any concrete or other effusion from the mucous membrane of the air passages. The child is seized all of a sudden, roused perhaps from its sleep, or

checked during the act of sucking, by a catch, or interruption of its breathing, more or less complete. It strives and struggles to inspire, but is apparently unable to do so; at length the effort is successful, and the breath is drawn in with a shrill whistling or crowing sound, like that which characterizes the inspirations of croup, or of hooping cough, and depending, no doubt, upon the same cause—a narrowing (in this complaint temporary) of the fissure of the glottis. *Spasmodic croup* is the most common of its names. It is the *thymic asthma* of the Germans. My late colleague, Dr. Ley, in a volume upon this curious disorder, published a short time before his death, adopts from Dr. Mason Good the appellation of *laryngismus stridulus*. Dr. Gooch called it *child-crowing*, a homespun term, which I much prefer to the somewhat pedantic and cacophonous title bestowed upon it by Dr. Good. The crowing noise, and its concomitant phenomena, take place in paroxysms, which vary in respect to frequency and severity, and which are separated by intervals of easy and natural breathing.

“When the closure of the chink of the glottis is not perfect, the child struggles for its breath: the respiration is hurried; the countenance generally bluish or livid; the eyes staring; and each inspiration is attended with a crowing noise. When the closure is more complete (and this state was found by Dr. Ley, whose words I am now quoting, to be much the most frequent, at the commencement of the paroxysm) the function of respiration is entirely suspended for a while; there is an effectual obstacle to the admission of air. The child makes vehement struggles, by some termed convulsive, to recover its breath. At varied intervals, from a few seconds up to a minute, or upon some occasions nearly two minutes, air is at length admitted through the glottis, now partially open; and this rush of air, passing through a very narrow chink, produces the peculiar sound. To these symptoms not unfrequently succeed a fit of coughing or crying, which terminates the scene: or, if the glottis be not thus partially open, the child, at the end of from two to three minutes at the utmost, will die suffocated. Pallid and exhausted, it falls lifeless upon its nurse’s arms; and it is then that the child is generally said to have died in a fit.”

Sometimes, but not always, with the symptoms now described there is a contracted state of the flexor muscles of the thumb, fingers, wrist, ankle, and toes; giving to the foot an appearance approaching to that of club-foot.

Now, till very lately, most of those persons who had learned not to confound this child-crowing with true croup, were of opinion that it depended upon *cerebral* disease, or disorder. This was the doctrine of Dr. John Clarke, who has left a very good description of the complaint, which he called “a peculiar species of convulsions.” Dr. Ley doubted the correctness of that notion, and fancied that the bending of the limbs resulted rather from feebleness or paralysis of the extensor muscles, than from spasmodic contraction of the flexors. It was obviously a great point to make out, whether the disorder depends upon pressure *within the head* or not. Our treatment will be regulated by what we know, or believe, in that respect. But what was chiefly original, and very interesting, in Dr. Ley’s views concerning this bastard sort of croup was this, that he attributed the temporary closure of the glottis to pressure made by enlarged glands in the neck or chest upon the recurrent nerve, or upon some part of the eighth pair: “subverting the exact antagonism by which the glottis is automatically and involuntarily kept open, and allowing its margins to come together, and to occasion the peculiar kind of inspiration so much like that of croup.” Dr. Ley looked upon the affection altogether as more allied to paralysis than to convulsive movement. This certainly was a very original, but, I conceive, a mistaken view of the matter; I must refer you, however, to his book for the facts and reasonings upon which it is founded. The important practical fact announced by him was the frequent connexion of child-crowing with tumefaction of the glands in the neck and chest, and with the entanglement of the pneumo-gastric nerve, or its branches, among these glands. “Scarcely an instance (says he) has occurred to me since my attention has been very much directed to the subject, in which there has not been the strongest foundation for the belief that either the glandulæ concatenatæ of the neck, or the thoracic absorbent glands, had become morbidly enlarged.”

Not long after the publication of Dr. Ley’s book, this curious and intricate knot was somewhat further untwisted. Its complete solution is of yet more recent date. Dr. J. Reid ascertained, by a well-contrived set of experiments, that the inferior

laryngeal (or recurrent) nerve, is an efferent or motor nerve, by which nearly all the movements of the larynx are regulated; and that the superior laryngeal is an afferent or incident nerve. We may easily conceive, therefore, how pressure upon, or irritation of either of these nerves, may affect the aperture of the glottis. If the superior laryngeal nerve be implicated, the impression is communicated to the spinal cord, and thence reflected, through the recurrent, upon the laryngeal muscles. Irritation of the *gastric* ramifications of the *par vagum* may have the same result. It is an observation of Dr. John Clarke's, that the attacks "very commonly take place after a full meal." Nay, it seems probable that not only *any* of the afferent fibrils of the eighth pair of nerves, but those of the fifth pair also may have a similar exciting power; for a transient crowing is readily produced in some children, by exposure of the surface of the face and chest to a breeze of wind, or by their being suddenly tossed in the arms of a nurse. We must even suppose that the effect produced upon the central cord may, by reflexion, influence other muscles, and cause the carpedal contractions that are so frequently to be noticed. Again, if the recurrent nerve itself be pressed upon, or interfered with, undue contraction or paralysis, according to the kind and degree of interference, will be likely to ensue, of the muscles belonging to the glottis. Spasm of those muscles would close the chink, and stop the breath. And Dr. Reid has shown that their palsy, except while the breathing is perfectly quiet and tranquil, sensibly impedes inspiration, and alters its character.

It appears, therefore, that the ingenious view taken by Dr. Ley of the special pathology of this child-crowing disorder, or croup-like convulsion, merges in the more general principles of reflex function advanced by Dr. Marshall Hall.

At the same time it is interesting to observe how Dr. Ley's theory harmonizes with what has been noticed of the predisposing causes of this crowing inspiration. In the first place, it is often manifestly connected with *dentition*. Now one effect of dentition is the production of glandular swellings of the neck; which happen even in the absence of all strumous taint, but with still more likelihood if any such taint exist. And thus he explains the fact, that the disorder has appeared in the most robust as well as in the most delicate infants. Thus also he explains another well-known fact, viz., that, when child-crowing accompanies painful dentition, the symptoms do not vanish instantaneously, as if by magic, the moment that the tooth starts through the gum; but pass off by degrees. Dr. Ley remarks that, "after the gum and enveloping membrane of the tooth have been relieved from swelling and inflammation by the free use of the gum-lance, *some time* is still required for the irritation and tumid state of the cervical glands to subside." It is not improbable that the gingival irritation alone may sometimes suffice, through the channel of the trifacial nerve, to determine the reflex spasm.

Again, this child-crowing is found to occur in connexion with excoriations behind the ears, and with inflamed and irritable scalp; and these complaints very frequently lead to enlargement of the absorbent glands of the neck, which enlargement may thus form an intermediate link in the chain of events. And upon some occasions Dr. Ley has had strong reason to suspect that bronchitis, or other *disease of the lungs*, has occasioned enlargement of the bronchial glands, and so given rise to the crowing inspiration.

I think that Dr. Ley has made out fair grounds for his view of the pathology of what is called spasmodic croup. But it is too partial and limited a view. Again, the alleged connexion between child-crowing and *cerebral* disturbance is not a mere fancy, although its bearing may have been sometimes misapprehended. The cerebral disturbance is mostly the consequence, more rarely the cause, of the impediment to the function of respiration.

[We doubt the correctness of Dr. Ley's views, as well as the views of those who refer the disease to enlargement of the thymus gland. For an examination of the facts connected with the pathology of *laryngismus stridulus*, the reader is referred to the Editor's Treatise on the Diseases of Children. — C.]

The practical *fact* which you have to remember is, that croupy breathing may occur, and return in paroxysms, when there is no croup. And the practical *lesson* which you have to learn is, how to discriminate between these two similar, yet diffe-

rent disorders. I have already specified the distinctive characters of cynanche trachealis. The complaint that copies it may be known by its sudden accession, and its sudden departure; by the freedom of breathing in the intervals between the paroxysms; by the absence of fever, of preceding or present catarrh, of hoarseness, and of any abiding cough. The diagnosis, easily enough reached when these points are sufficiently attended to, will be still more sure, if you discover enlarged glands in the neck: or hot, tense, and tender gums.

According to Dr. Clark, "convulsions of this description seldom, if ever, occur after the expiration of the third year of a child's life."

It must be unnecessary for me to urge the *importance* of the diagnosis. Those active measures which befit the outset of the inflammatory disease, would be misplaced and mischievous in the other. It was the result of Dr. Ley's experience that "those children have upon the whole a much better chance of being preserved, who are not subjected to very severe discipline, than those who, in compliance with the prevailing doctrine, have been treated by very copious bleedings, large doses of calomel, and such other remedies as the supposition of the invariable dependance of the disease upon cerebral turgescence, or excitement, has suggested."

Do not, however, imagine, from what I have just been saying, that this disorder, child-crowing, is a trifling disorder, and unattended with danger. It is really a perilous, as well as a terrifying condition. The respiration is sometimes so long suspended that death takes place in the paroxysm. And each paroxysm is accompanied by a tendency to stagnation and congestion of blood, in the brain, lungs, and heart: a tendency which, by its frequent repetition, may lay the foundation of serious and fatal disease in one or other of those vital organs.

The treatment of this affection must depend a good deal upon the nature of the predisposing and exciting causes. To go into it fully would require that I should speak of the mode of cure in painful dentition, in eruptive complaints about the head, in certain pulmonary and cardiac diseases, in disorders of the digestive organs, and in all those conditions which are apt to cause enlargement of the catenated or bronchial glands: or to fret, in some other way, the pneumogastric nerves.

In addition to the special methods of treatment which these complaints may severally need, great care must be taken, in all cases, to regulate the state of the bowels, and of the skin. *Fresh air* also is a powerful adjuvant; and sometimes of itself a sufficient remedy. Change of place, therefore, and especially a removal from the air of a city or town to the purer atmosphere of the country, should be urged whenever it is practicable.

Dr. Wm. Budd has recently announced that in ten or twelve instances, he has observed a speedy subsidence of this disorder under from five to ten grains of the phosphate of lime, administered three times a day, in chalk mixture. Whether the success of this remedy was due to its antacid properties, deserves further inquiry.

In the paroxysm itself the warm bath might be useful, if it could be got ready in time. The application to the throat of a large sponge from which hot water has just been squeezed, is a more accessible, and often a very effectual expedient. Sprinkling the face and chest freely with *cold* water will sometimes unlock the spasm, and set the little sufferer free.

I should have stated, that Dr. Ley's peculiar views were amply supported by the researches that he had made into the morbid anatomy of this affection. Had he lived, I should have had it in my power to show you some very beautiful and interesting preparations, illustrative of the connexion of the disorder with enlarged glands, which had come to press upon, or stretch, the par vagum, or its branches. As it is, I can only show you the published engravings from some of them, appended to his book. But for a full view of the pathology of laryngismus generally, I recommend you to study Dr. Marshall Hall's first essay *On the Theory of Convulsive Diseases*.

[SPASMODIC LARYNGITIS—Under the head of "child-crowing or spurious croup," Dr. Watson has confounded two very distinct diseases. One occurs, most commonly, entirely independent of inflammation in any portion of the air-passages, and consists simply in a spasm of the glottis, the result of a reflex action, through the excitatory property of the nervous system, of various irritations of the gums or digestive apparatus, or of the action of external agents, or mental emotions. This is the affec-

tion known as *laryngismus stridulus*. The other disease differs in nothing from genuine croup, excepting that the inflammation is less intense, and seldom extends into the trachea; the exudation is of a more muco-form character, seldom adhering long enough to the inflamed mucous surface of the larynx to become converted into false membrane. This form of laryngeal disease has been termed *catarrhal croup*, *false croup*, and by some *spasmodic croup*: we prefer the name *spasmodic laryngitis*, given to it by Rilliet and Barthez.

The attack of spasmodic laryngitis is usually preceded by slight catarrhal symptoms; coryza, watering of the eyes, a sense of chilliness followed by flushes of heat; slight hoarseness and some cough. These symptoms may continue for twenty-four or forty-eight hours before a paroxysm of the disease is observed. In general this occurs at night; the child being suddenly awake from its sleep by a sense of impending suffocation. He starts up in a sitting posture, or throws himself forwards on his knees. He cries out that he is choking, seems anxious for air, tears off every covering from his throat, and pushes away all who surround or offer to assist him. The face becomes swollen and of a dark red or violet hue, the eyes projecting and humid, and the expression of the countenance extremely anxious. The inspiration is long and hissing; and so loud as occasionally to be heard in an adjoining apartment. There is also, at intervals, a frequent hoarse cough. The voice is constrained, but seldom whispering or abolished. The pulse is quick, and the skin hot. In a short time the paroxysm ceases, and the patient falls asleep. The disease may be confined to a single paroxysm. More commonly, however, the child continues during the ensuing day tolerably well, excepting perhaps that he is somewhat hoarse and has an occasional short barking cough, with or without expectoration; and on the succeeding night is again attacked with a paroxysm as on the night previous. The disease may continue thus, with one or two paroxysms each night, for several days, when the paroxysms will cease to recur, and the cough and other symptoms speedily disappear. In some cases, however, the paroxysms continue to recur at shorter intervals, and gradually augmenting in intensity, the patient dies from asphyxia, or, in other cases, after one or more paroxysms, he becomes affected with the utmost inquietude, with almost constant nausea and repeated vomiting, with symptoms of great exhaustion, cold extremities, and a small frequent pulse, and soon dies. Usually, however, the disease is one very readily controlled, and has seldom a fatal termination.

Spasmodic laryngitis is very liable to recur after three, six, nine months or a year, or whenever the child is exposed to cold and damp, or during seasons marked by sudden vicissitudes of temperature.

Barthez and Rilliet have pointed out the dependence of the disease upon actual but slight inflammation of the larynx. This opinion is based upon the fact that its attacks generally follow sudden exposure to cold, and by its being preceded by catarrhal symptoms, and being attended by some degree of febrile excitement. In connection with this mild bronchitis there occurs also a spasmodic affection of the glottis, to which they attribute the paroxysms of suffocation. That the disease is always attended with some degree of laryngeal inflammation also is evident from the result of post-mortem examinations. In the few instances in which an opportunity has been afforded for an examination after death, traces more or less decided of inflammation of the mucous membrane of the larynx have generally been detected—even when no traces of increased redness are present, the secretion of the membrane is usually found to be augmented, and of an opaque yellowish or reddish colour. When, as sometimes happens, death takes place suddenly during a paroxysm, it is probably the result of asphyxia, caused by a complete spasmodic closure of the glottis.

The disease usually occurs in children from ten months to eight years of age, but more frequently between two and five years. It occurs more often in boys than in girls.

There is in some families a peculiar predisposition to the attacks of spasmodic laryngitis—nearly all the children becoming affected with it as they attain the age of between two and three years. Though generally sporadic, it occasionally prevails as an epidemic.

Its occasional cause is almost exclusively exposure to cold and damp, or sudden alternations of temperature. After an attack has occurred, the paroxysms may be excited by any sudden or violent mental emotion.

The prognosis in this disease is generally favourable—but when the occurrence of the paroxysms is prolonged beyond the third day, and they constantly augment in intensity—especially when they are succeeded by great restlessness, nausea and vomiting, when the pulse becomes soft and feeble, when a frequent suffocative cough remains, and the patient's strength gradually diminishes, an unfavourable termination is to be apprehended.

The disease with which spasmodic laryngitis is most liable to be confounded, is pseudo-membranous or genuine croup.

The following comparative diagnostic peculiarities, borrowed partly from M. Valleix and partly from MM. Rilliet and Barthéz, will enable us very readily to distinguish the two diseases—

In Croup.

There is fever of variable intensity—*pseudo-membranous angina*, and slight hoarseness.

There is a gradual increase of the hoarseness, and sooner or later a hoarse cough.

The fever does not remit; the cough becomes hollow and feeble, and the voice faint or extinct.

The disease is sometimes attended with an expectoration of false membrane.

The dyspnoea constantly increases, the croupal sound continues during the paroxysms—finally the voice and cough become extinct.

In Spasmodic Laryngitis.

The symptoms of invasion are slight—there are a slight catarrh, and a cough somewhat hoarse—the throat is unaffected—sometimes there are no prodroma.

The attack is sudden—usually at night.

Between the paroxysms the patient appears well—the fever disappears or declines—the voice is rarely extinct.

There is an expectoration of mucus.

The paroxysms of the disease decrease in violence.

The proper treatment of a case of spasmodic laryngitis will depend in a great measure upon the violence of the attack and the age of the patient.

When there are decided indications of laryngeal inflammation, and the spasmodic paroxysms are intense and prolonged, the application of leeches to the throat, in numbers proportioned to the violence of the symptoms, and the age and strength of the child, will be proper. In robust children of five years and upwards, bleeding from the arm will often be productive of the best effects. In no case, however, will it be proper to draw much blood either from the arm or by leeches; nor should the operation be repeated at short intervals, or too late in the disease—in the milder cases the abstraction of blood will not be demanded.

On the first accession of the disease it has been advised by Lehmann to apply a sponge, dipped in very hot water, and then carefully squeezed out, upon the anterior part of the neck, and leave it a moment in contact with the skin—the application being repeated at short intervals. This will produce a redness of the surface, and a general perspiration, which is to be promoted by giving some mild tepid diluent. By this simple procedure the paroxysm, we are told, together with all the leading symptoms of the disease, may be cut short.

An emetic given at the commencement of the attack, when followed by the warm bath, and sinapisms to the extremities, will generally abate the violence of the paroxysm, and shorten its duration. The exhibition of an emetic, or of small nauseating doses of ipecacuanha, in the intervals of the paroxysms, when considerable hoarseness of the voice, and a frequent short barking cough continue, will generally be found to remove very promptly these symptoms, and prevent their recurrence.

The bowels should always be attended to, and if not freely and regularly open, a dose of calomel, followed by castor oil or magnesia, will be proper.

Blisters to the neck or chest, or between the shoulders, are recommended by some writers. We have seldom seen much benefit to result from their application. When employed they should be allowed to remain on only for an hour or two; and when removed the part occupied by them should be covered with a soft emollient poultice.

In violent cases, subsequent to depletion and the use of the warm bath, much benefit has been derived from the administration of assafœtida, either by the mouth or by enema, a few hours after the paroxysm has terminated. Covering the breast with an assafœtida plaster we have, also, found to be decidedly beneficial.

Several of the German physicians recommend in the highest terms the use of musk in this disease. Wendt gave it in the dose of a grain every hour.

When the paroxysm, from its length and violence, threatens the destruction of the child by asphyxia, the operation of tracheotomy should be performed without delay.

During the entire continuance of the disease the child should be warmly clad, and kept in a warm, well ventilated room. His diet should be light, and of easy digestion, and his drinks should consist of weak, lukewarm lemonade, barley or toast water. The utmost care should be taken to preserve the patient in a state of perfect tranquillity. During the paroxysms he should be supported in an erect position; all covering or ligatures being removed from about the neck.

There is another affection of not unfrequent occurrence, to which attention has been recently directed by Dr. Behrend (*Journ. der Kinderkrankheiten*), that has no doubt been frequently mistaken for spasmodic laryngitis. It is a spasmodic cough of a peculiar character, to which children are liable, and which occurs only during the night.

This affection is most generally observed in spring and winter; it, however, also frequently occurs during the autumn, and but rarely in summer. It is seldom, if ever, observed in infants at the breast, but occurs at every subsequent period of childhood, and more frequently in boys than girls. There is no cough whatever during the day, not the slightest catarrhal symptoms, and, when put to bed, the child falls into a sound quiet sleep at the usual hour. In the course of a few minutes, however, it becomes restless, and before awaking, coughs violently. It now commences to cry, and the cough becomes more and more severe, until, in some cases, it produces vomiting; after one or two hours of suffering, the child again falls asleep, and passes the remainder of the night quietly. The cough returns at the same hour the following night, and continues sometimes for weeks and even months; finally, it begins to diminish in violence, the fits become of shorter duration, and occur at a more advanced period of the night, so that the length of the sleep enjoyed previously to its coming on, is gradually prolonged:—at length the cough disappears entirely and spontaneously. The subjects of this affection are pale, readily fatigued, and troubled with a coldness of the feet towards evening; they eat and play, however, as usual, and appear otherwise to enjoy good health. The nocturnal cough has frequently a catarrhal character, and is generally accompanied with a mucous rattle; sometimes, the cough is dry, croupy, and whistling; the kinks are short, isolated, and uniform, and may recur every five minutes, or extend only to one or two.

This nocturnal periodic cough cannot be mistaken for genuine croup—which has well marked symptoms; and it may be distinguished from spasmodic laryngitis by the complete intermission which follows the paroxysms, by its not being preceded by any catarrhal symptoms, and by the entire freedom from fever throughout the attack. It may be distinguished from whooping-cough from the latter being almost always epidemic, and occurring as well during the day as during the night, and always accompanied with a peculiar dyspnoea. In the nocturnal periodic cough there is no true appearance of suffocation; the children do not awake suddenly, as in a fit of asthma or spasm of the glottis, but they awake slowly, after having coughed several times during sleep. It most nearly resembles the cough of catarrh or bronchitis, but it is distinguished from those by the entire absence of the physical signs, and by the nocturnal periodicity of the fits, which are followed by complete remission.

Dr. Behrend considers this cough to depend on an affection of the nerves, and bases this opinion chiefly on the symptoms, and on the circumstance of its having frequently appeared after an epidemic of whooping-cough, and whilst intermittent fevers were very prevalent among adults. This latter remark has been made by several physicians whose attention was drawn to this cough by Dr. Behrend.

The prognosis, we are told, is always favourable. In one case the periodic cough was followed by bronchitis, but this was probably merely accidental. In another case there was repeated epistaxis.

The disease, upon the whole, is generally more troublesome than serious, and demands no active treatment. Gentle purgatives, as manna with the tincture of rhubarb, given in the evening, with attention to diet and regimen, are recommended. A drachm or two of the liq. acetatis ammoniæ, in a little sugar, may also be given, before putting the child to bed. One physician found small doses of quinia, given at bed-time, of great service; another found slight irritation of the skin, chiefly by means of pediluvia, and friction of the soles of the feet with roasted onions, and even enveloping the limbs, after the manner of Preissnitz, beneficial. — C.]

LECTURE XLVII.

Diseases of the Thorax. General observations. Dyspnoea. Cough. Methods of exploring the physical conditions of the chest, by the senses of sight, touch, and hearing.

FROM the throat—and especially from that part of it with which we were last occupied—the transition is natural and immediate to the *thorax*. Now the interior of the chest is the theatre of numerous and most important morbid changes. Within that cavity are lodged two of the three organs most essential to life. The heart, lungs, and brain, have been said, by a bold figure of speech, to constitute the tripod of life: and the two former are planted in the thorax. In the same region of the body lie also the greater blood-vessels, and many other parts of scarcely less consequence. With respect to the heart, its alternate swinging movement cannot long stop, and the patient continue to live: and a pause of three minutes in the play of the lungs would in most cases be irremediably fatal. And lesser impediments to the free working of either of these two vital organs are productive of much danger and distress; and lead often to consecutive changes of a very serious kind, in various other portions of the body.

These parts, of which the function is so indispensable, and of which the disorders are so grave and perilous, are encased in such a manner by the ribs and other boundaries of the chest, that they can neither be seen nor handled. And until a very late period in the history of medicine—until our own times, in fact—the diagnosis of the formidable maladies that befall the viscera of the thorax was exceedingly uncertain and imperfect. Physicians were able, indeed, by the observation of indirect symptoms, manifested through the general system—by remarking the presence of inflammatory fever, I mean—to infer that inflammation had been somewhere lighted up: and symptoms that denoted disturbed function of the respiratory apparatus—cough difficult breathing, or local pain—might suffice to apprise them that the inflammation was situated within the chest. But what tissue it affected, where was its exact place, what was its extent, or what were its physical consequences—these were points concerning which they had no means of obtaining any precise knowledge. “Under the title of pneumonia or pneumonic inflammation,” says Cullen, “I mean to comprehend the whole of the inflammations affecting either the viscera of the thorax, or the membrane lining the interior surface of that cavity: for neither do our diagnostics serve to ascertain exactly the seat of the disease, nor does the difference in the seat of the disease exhibit any considerable variation in the state of the symptoms, nor lead to any difference in the method of cure.” You will see, as we proceed, how very inaccurate this last statement would be, if it were made under our present mode of investigating these diseases. “Pneumonic inflammation (he continues) however various in its seat, seems to me to be always known and distinguished by the following symptoms:—Pyrexia, difficult breathing, cough, and pain in some part of the thorax.”

I state these things to you—who do not recollect the time, as I do, when no medical man in this country could, with truth and candour, say more of his knowledge of diseases of the chest than Cullen said—that you may the better estimate the exceeding value of the discovery of what is called the method of auscultation, for the detection and discrimination of disease; and most particularly of thoracic disease. In the present day we are able to obtain more exact information respecting the disorders of the parts contained within the chest, than of any other internal and therefore invisible parts of the body. Indeed, in a vast number of instances, we can tell, as accurately as if we saw them, the actual condition of the thoracic viscera: can follow, step by step, the successive processes of disease or of repair, in which they are involved. We can penetrate beyond the symptoms which denote deranged function, and comprehend those much less fallible signs which arise from alterations of structure. And this vast addition to our pathological knowledge has been given us by the simple application of one of our five senses to the investigation of disease, the sense of hearing, which

for so many centuries had been (strangely as it now seems) neglected, or but little used. Through the aid and use of the ear it has come to pass that those diseases which, besides being the most common and the most destructive, were also the most obscure, are now better understood than the diseases of any other internal part whatever.

The direct symptoms which arise out of the changed conditions of the parts affected in thoracic complaints, are so mixed up with all that we know or can learn of such complaints, that what in other cases is called the morbid anatomy of a disease, becomes, here, a part of its descriptive history. I shall not say, therefore,—as in regard to many other maladies I am obliged or I find it convenient to say—so and so are the symptoms; and afterwards, so and so are the morbid appearances: but I shall describe the morbid conditions in the outset, as the only way of rendering the symptoms which result from them intelligible.

But before I enter upon the subject of auscultation, it may be useful to make a few remarks upon those symptoms of thoracic disease which were previously known, and which depend upon, or rather which express, derangement of the pulmonary functions.

One of the most constant, and obvious, and distressing, and instructive of these symptoms, is embarrassed or laborious breathing: what is technically called *dyspnœa*. You know that by a healthy adult, under ordinary circumstances, the act of respiration is performed, unconsciously almost, about eighteen times in a minute. There is one act of respiration for about every four beats of the heart. In various diseases this proportion is materially altered. The reciprocal movements, by means of which, in measured succession, air is drawn into and again let out of the lungs, are performed with hurry, or effort, or unusual slowness. *Dyspnœa* implies some deviation from the natural manner or rate of alternately expanding the thorax, and suffering it to collapse again: of inspiring and expiring: in one word, of breathing. The patient himself may, or may not, be conscious of this deviation. In most of the cases in which *dyspnœa* claims to be regarded as a symptom, he is conscious of it. Now upon what does this symptom depend? It may ultimately be referred to an altered proportion between the quantity of atmospheric air that reaches the lungs, and the quantity of blood that is sent into them, from the right side of the heart, to be converted from venous to arterial. That, doubtless, is at the bottom of almost every case of *dyspnœa*. Let me remind you that respiration is an automatic movement; subject, nevertheless, to the occasional control of the will. The pulmonary branches of the par vagum constitute the principal and constant *excitor*, as the nerves that supply the muscles of respiration are the *motor* links of the nervous chain by which the automatic movements are governed. It is believed that the presence of venous blood in the capillary vessels of the lungs forms the natural stimulus to the pulmonary part of the par vagum. In the ordinary breathing of a healthy person, this stimulus or impression is not felt: perhaps because, being slight and habitual, and exactly apportioned to the need of the individual, it is not attended to: or, it is at once appeased by the admission of air, and the corresponding change in the blood. But when that change is not immediately or perfectly accomplished, then arises the distressful sensation which everybody has felt, but which our own language has no one word to express. The French call it the *besoin de respirer*. The English phrase, *want of breath*, denotes the peculiar sensation equally well. It calls into exercise, frequently, the voluntary power of performing the mechanical acts of breathing—a power which is superadded to the automatic process.

Various are the ways in which the natural manner and frequency of the respiratory movements may be disturbed. They were fully considered when I was on the subject of death by apnœa. They all operate ultimately, by destroying the just equilibrium between the blood and air which meet to undergo mutual and chemical changes in the lungs. We have lately been considering certain diseases in which the difficulty and distress of breathing are often extreme. In croup, and in laryngitis, the only inlet for the air is narrowed at its very entrance: there is more blood passing through the lungs than can be arterialized under the ordinary motions of respiration: instinctive efforts take place to increase the quantity of air; to make up by more numerous acts of inspiration for the diminished amount of air introduced by each single act. For a time these compensatory efforts may suffice. But if the access of air be still

impeded, blood but half decarbonized begins to circulate through the arteries; and to linger and stagnate in the lungs: the lips become livid, and the skin grows dusky. Make, however, a free and timely opening in the pipe that should conduct air to the lungs, and the balance being restored between the blood in those organs and the air that reaches them, the dyspnœa is soon at an end. The quantity of blood being the same then, but the air inspired *too little*, there will be dyspnœa. The very same thing occurs whenever a portion of lung, from being spongy, is rapidly rendered solid. No air can then penetrate it: nor *perhaps* any blood: but the same quantity of blood as before arrives at the right side of the heart, and is transmitted thence through the pulmonary artery: and consequently those portions of the lungs which are pervious to blood and air, are supplied with blood in excess, and require air in excess: *i. e.* dyspnœa is necessitated. And you will perceive that similar consequences may arise from any pressure made upon the lung, obliterating in a certain degree its cellular structure; as by fluid collected in the pleura; by enlargement of the heart; by aneurism of the great vessels; by tumours of whatever kind, within the chest; or by pressure upwards against the diaphragm by reason of a distended abdomen, whether the distension be occasioned by disease, such as ascites, or by obesity, or by a full stomach, or by a gravid uterus. A like disproportion will ensue, if the free expansion of the thoracic cavity be prevented by pain, by disease or rigidity of its boundaries, or by palsy of its muscles through interruption of the nervous circle whereon their contractions depend.

But on the other hand the balance may be destroyed from the opposite quarter: the air admitted during a single ordinary inspiration being the same, the quantity of blood requiring to be converted from purple to scarlet may be augmented; and in that case also, in order to maintain the due equilibrium, more numerous acts of respiration must be performed: in other words, dyspnœa will arise. This is the case under brisk exercise: the pressure of the muscles upon the veins propels their contents with greater velocity towards the right side of the heart; the heart contracts more frequently in proportion as it is more rapidly filled with blood; a greater quantity than usual is sent through the pulmonary artery to the lungs; and the individual breathes more quickly, to supply this augmented quantity of blood with air: he is out of breath, in a state of dyspnœa. But this is not disease. Disease, however, will often have the same effect. The quickened circulation in fevers, any obstacle to the free passage of the blood from the heart into the arteries, will tend to gorge the lungs with blood, to destroy the requisite equilibrium between the air and the blood in those organs, and so give rise to dyspnœa.

Other conditions still may be mentioned, as predisposing to hurry of the breathing—a peculiar state of the nervous system; certain qualities of the blood;—but I need not dwell on these at present.

There are two important corollaries deducible from what I have now been stating. In the first place, you must perceive how intimately the functions of the heart and lungs are dependent upon each other; and that disease originating in either of these vital organs may readily be the cause of consecutive disease in the other. We shall have many examples of this before us as we proceed. It would afford materials for an interesting essay, this mutual relation between cardiac and pulmonary disease. At present I merely glance at it in passing.

In the second place, what I have said of dyspnœa must have sufficed to show you that, taken by itself, it has not much value as a diagnostic symptom. All that it tells us is, that the healthy and natural relation between the quantities of blood and of air in the lungs is disturbed: but to determine the cause of that disturbance—to decide whether the heart be in fault, or the lungs, or both, or neither—we must have recourse to other sources of information.

Cough is another of the symptoms mentioned by Cullen as denoting disordered function of the breathing apparatus. I need scarcely tell you that it is produced by closing the glottis, and then making a sudden and strong expiration. Its purpose is the dislodgement of mucus which may have collected in excess in the air-passages, or of any other source of irritation to the membrane lining those parts. To be effectual it requires the admission of a certain quantity of air, and the possession of a certain degree of muscular strength. I pointed out to you, in the last lecture, a remarkable exemplification of this: the boy whose case is described by Mr. Chevalier in the

Medico-Chirurgical Transactions, was dying of croup; was on the brink of being suffocated by the collection of mucus in his windpipe and bronchi, which mucus he was unable to expel; and he was unable, not from defect of muscular strength, but because he could not sufficiently inflate his lungs *beyond* the collected mucus. When an ample opening was made in his trachea, he drew in a strong breath, and coughed the mucus up *through the rima glottidis*. In old and feeble persons labouring under chronic bronchitis with profuse secretion from the mucous surface, strength is often wanting to cough the phlegm up; and they die suffocated.

But the sensation which prompts to the act of coughing may arise from various other causes besides the accumulation of mucus in the air-passages. Any slight irritation about the glottis; a long, trailing and tickling uvula; the inspiration of irritating vapours; pressure of any kind upon the respiratory organs; may any of them produce cough. Nay, it sometimes is provoked by sympathy with other parts; an instance of which we have in what is called a stomach-cough. Some morbid condition, some irritation, of the stomach exists, which being appeased, the cough ceases. You will recollect the name and the functions of the *pneumogastric* nerves. We have, in the fact just mentioned, another example, in addition to those which I glanced at in a former lecture, of irritation of the sentient extremities of one branch of a nerve, declaring itself by uneasy sensations referred to other branches of the same nerve. For these reasons, therefore, cough is not more diagnostic of particular diseases situated in the thorax, than is dyspnoea. There are, indeed, certain varieties of cough, as there are certain modifications of the breathing, from which we may obtain very useful information even in respect to the nature and seat of *some* diseases: and these varieties and modifications I will point out as I go along.

Let me admonish you, also, before we come to auscultation, not to fall into an error which has been too common; that of trusting entirely to the ear in the investigation of thoracic disease, to the exclusion or neglect of those phenomena which are perceptible by the eye, or by the hand; or of those indirect revelations which are furnished by the condition of other parts and functions, or by the previous history of the patient. Even before the discoveries of Avenbrugger and Laennec, physicians were too remiss (if we may judge from their writings) in what may be called the mechanical exploration and notice of the actions of respiration. A good deal may be learned, sometimes, by merely placing one's hand upon the chest, or belly, as I shall explain more particularly by and by: and a great deal, also, may be made out, in some cases, by the simple inspection of those parts, when they are uncovered. You may see, for example, that the ribs, in respiration, scarcely move at all, while the belly rises and falls alternately with the descent and ascent of the diaphragm. This is called *abdominal respiration*. It may arise from a painful condition of the intercostal muscles, or of the pleurae, rendering the patient *unwilling* to elevate his ribs; or it may arise from disease of the spinal cord, between the origins of the phrenic nerve and of the intercostal nerves, rendering the patient *unable* to raise them; or the same *inability* may result from disease of the lungs themselves. The symptom may guide us at once to the seat of the malady. Again, the breathing may be entirely *thoracic*, no motion of the abdomen taking place; and this may depend upon an affection of the diaphragm, or of the pleura which is reflected over it; or upon disease, accompanied with tenderness, within the abdomen — upon peritonitis for example; or upon mere distension of the abdomen. Or, by looking at the naked chest, you may see that one side of it moves, and that the other moves less, or does not move at all: and the motionless side may be of the natural size as compared with the other, or it may be flattened and contracted, or it may be round and bulging; and most important conclusions, and most important indications of treatment, will flow from a knowledge of these circumstances. The general form of the chest is also instructive. Never neglect, then, to examine the thorax, in cases where it is supposable that the disease may be seated in that part of the body, by your *eye*, as well as by your *ear*. The eye needs but little training to enable it to perceive and comprehend those signs which are within its sphere: the ear, unfortunately, requires to be carefully educated. I will just remark, further, that in the case of females no indelicate exposure of the person need be made. In most instances the morbid conditions I have been adverting to may be recognised through a thin linen covering.

Auscultation signifies the investigation of internal diseases through the sense of

hearing : and it is especially applicable, for reasons which I either have stated or will state, to the study of *thoracic* diseases. In its full meaning it includes all that we learn by listening to a cough, and all that we gather by striking the chest, and attending to the resulting sound. But in general, the term *percussion* is used to express this last mode of eliciting information, although the information is conveyed through the medium of the ear : while the term *auscultation* denotes the art of distinguishing diseases by hearkening to internal sounds, by means of the ear applied to the naked or thinly covered surface of the body ; or by means of some conductor of sound interposed between the ear of the listener and the person of the patient. In the first of these two modes the auscultation is said to be *immediate* ; in the second, *mediate*. By percussion we ascertain the degree of resonance, or want of resonance, of the part struck : by auscultation we learn the qualities and modifications of the voice, as reflected through the chest ; and of the breathing ; and of the sounds of the heart. The invention of the method of percussion we owe to a German, Avenbrugger, who wrote an excellent treatise upon it, which was brought into notice by Corvisart, who translated it. For the more brilliant discovery of auscultation we are indebted, as everybody knows, to Laennec.

Now it will save us much trouble, and conduce, I hope, to your future progress as practical auscultators, if, before I speak of any of the diseases of the chest, I premise some general observations respecting these modern methods of examining the human body, with the view of detecting and discriminating its diseases. Indeed, I could not make myself intelligible unless I did so.

And first, with respect to percussion, which you will please to recollect is nothing else than auscultation of, or listening to, sounds which we ourselves artificially and purposely produce.

You know, every child knows, by daily experience, that different substances, when struck, give out very different modifications of sound. If you strike a drum, you get one kind of sound ; if you strike a brick wall, you get another. The one is loud, trembling as it were, and prolonged ; the other dull, short, and flat. But why should I attempt to describe in words things which are familiar to you already ? Bodies that are solid, or inelastic, give the dull flat sound in proportion to their solid thickness, or their want of elasticity. On the other hand, hollow vessels, *i. e.* vessels containing air, with thin, firm, elastic boundaries, give out a sound more or less approaching in its qualities to that of a drum : the sound is called a *hollow* sound from that circumstance. If you have a wooden cask containing air only, it is resonant when struck : fill it half full of water, and the lower part will render a flat sound, the upper empty portion a hollow sound ; less hollow, however, than when the vessel contained no water : fill it up with water, and the *whole* is dull on percussion : pour out the water, and fill it loosely with wool—it will still be resonant, though in a different and less clear note than when it held air alone.

Now this experiment may be transferred to the human chest, which is a cavity, bounded by firm, thin, tense, and elastic walls, and containing, in its natural state, the spongy lungs, which are full of air ; and other parts that are solid, whereof the heart is the chief. If you strike the surface of the chest (it requires a little knack to do it properly), and if the blow fall over a portion of healthy lung, you will produce a resonant or hollow sound. If the lung be not there, if it be pushed aside, and its place supplied by some more solid or inelastic substance, by fluid for example, you will hear a dead sound. So you will if the lung *be* there, but has lost its spongy character, is void of air, and somehow or other solidified. But you may have a resonant sound, though the lung is in a state of disease ; nay, though the lung is not there : so that percussion alone cannot always be depended upon. I shall tell you, hereafter, how to guard against being misled by it in such cases. Again, if you strike over the region of the heart, you will get a positively dull sound, or at any rate a much duller sound than in most other parts of the chest.

It is really a singular thing, that this method of searching for indications of disease, and of health, should have been so long neglected or overlooked in our profession. I am sure that I had a practical acquaintance with the principle of percussion long before I knew anything of physic ; and so, I make no doubt, have most of you. Many a time, when wishing to know whereabouts I might drive a nail firmly into a wall, I have tried with the hammer to find which was brickwork, and which

was wooden joist; and percussion is an art in daily use for similar purposes, with carpenters and bricklayers. Yet it does not appear to have been thought of by physicians till the middle of the last century, when Avenbrugger, after studying its results, "*inter tædia et labores*," for seven years, published at Vienna his "*Inventum novum, ex percussione thoracis humani, ut signo, abstrusos interni pectoris morbos detegendi*." This was almost totally neglected, however, until, as I stated before, Corvisart's work on diseases of the heart brought it into general notice.

Avenbrugger and Corvisart, and indeed everybody who used percussion at all, until a very few years ago, employed *direct* percussion: that is, they struck the chest with the extremities of their fingers. More recently, *mediate* percussion has been introduced into practice, by M. Piorry. In *mediate* percussion some solid substance is placed upon the spot, the resonance of which is about to be explored, and the blow is made upon that substance, which is called a *pleximeter*—a stroke-measurer. A round thin plate of ivory, laid flat upon the surface, is the most common sort of pleximeter; or metal, or wood, or leather, or india rubber, may be employed. Many persons, and I am one of them, use no other pleximeter than the fingers of the left hand.

I shall explain, as briefly as I can, the method of employing percussion, and the cautions requisite to render it an effectual and a true interpreter of the state of the parts beneath the stricken surface.

The position of the patient is of some consequence. It should be one that is convenient to the examiner, and not inconvenient to himself; and it should be one calculated to render the part struck as firm and tense as possible. The best position of all is a sitting position, on a firm chair. But you may percuss a patient very effectually as he sits up in bed, or while he stands, or some parts even when he is lying down. A good deal is said,—more, in my opinion, than is necessary,—about the effect of curtains and so forth, in deadening the sound. I do not believe they will ever interfere with your conclusions, especially as we learn more from comparing the sounds given out upon percussing the corresponding parts of the opposite sides of the chest, than from the absolute resonance or want of resonance of any single part. But there are some exceptions to this; and if your patient can be made to sit on a chair in the middle of the room, so much the better.

Then, if you are about to percuss the front of his chest, let him suffer his arms to hang loosely down, and let him throw his head back. If you desire to explore in this way the lateral portion of the thorax, he may place the hand of that side upon his head, and lean a little to the opposite side. If you would know how the posterior part of the chest sounds, he may lean forwards, let his arms hang loosely between his knees, and bend down his head.

Next, as to the mode of percussing. For direct percussion, the ends of the fingers of the right hand should be brought together, and into a line with each other, so that no one of them may project beyond the rest; and care should be taken, first, to compare the sound produced by striking any part of the chest on one side, with that produced by striking the corresponding part on the other side. It follows from this rule that we should not examine all the points on one side before passing to the other, because we should thus lose the remembrance of, and the power of accurately comparing, the sounds obtained from corresponding points. It is best to strike first on one side of the body, and then on the corresponding spot of the other side. It follows also that we are not to compare the result of percussion on one of the *ribs*, with the result of percussion on one of the *intercostal spaces*. The blow should fall *upon* the rib, and *parallel* to it.

A second point requiring attention, is the state of the chest in respect to the act of breathing. If one side be percussed after the movement of inspiration, and the other after that of expiration, some little difference in the resulting sounds will be manifest, even in the healthy condition of the thorax. And this might mislead. Let corresponding spots on the two sides be therefore both struck, either while the chest is expanded, or while it is collapsed, or while the patient holds his breath.

Thirdly, you must take care to strike the corresponding parts at the same angle, and not with the fingers perpendicular to the surface on one side, and inclined obliquely to it on the other: also to strike corresponding parts with the same degree of force. And the blow should not be hard enough to give the patient pain; indeed

such a blow would not produce a good sound. It should be smart and quick; the ends of the fingers should not *remain* on the chest. Under some circumstances, however, the patient cannot bear to be percussed at all.

These latter cautions are most necessary when *direct* percussion is employed; over which *mediate* percussion has, however, many advantages. Some of these are obvious. In the first place, the space examined by mediate percussion is very exactly defined and limited. Secondly, you may strike the pleximeter much more forcibly than you could strike the unprotected body, and so produce a more decided sound. Even when the surface is morbidly sensitive, or the patient unusually irritable, so that percussion in the ordinary way cannot be performed at all, it may generally be done through the pleximeter. A third and very great advantage is, that mediate percussion is available when made over certain parts where, even although there may be no pain occasioned by it, ordinary immediate percussion is attended with no useful result. Parts, I mean, where there is much fat, and parts which are fleshy, or œdematous. If the pleximeter be pressed firmly upon these parts, even upon the mamma in females, the hollow sound is attainable; whereas, if they were struck by the fingers, the sound would be perfectly dull. Mediate percussion may be applied also, with effect, through the clothes.

I say that a convenient way, and one which I find quite sufficient, of employing mediate percussion, is by making a pleximeter of the finger, or fingers, of the left hand; taking care that they are closely in contact with the subjacent parts, and *similarly* applied to corresponding spots, and that the backs of the fingers be outwards. Piorry declares, indeed, that the resonance produced by this mode is scarcely one-tenth part so great as that elicited by using a thin, solid, and elastic plate. For all practical purposes, however, I am certain that the finger, as it is the readiest, so also is it a very satisfactory and sufficient pleximeter. It has, moreover, this positive advantage, that the sound made by striking *it* is not loud, and does not obscure or interfere with that which depends upon the condition of the chest.

It is right that you should be aware of differences of sound which belong to the individual. *Cæteris paribus*, the sound given out on percussion is more resonant during *inspiration* than during *expiration*; in childhood and youth than in middle age; in middle age than in old age; in females than in males; in thin persons than in fat; and, *they say*, in nervous irritable people than in those of a contrary temperament.

And it is still more necessary that you should be aware of differences of sound given out, in health, by different parts of the surface of the thorax, *in the same individual*. And in order to explain this more distinctly, and for the sake of reference hereafter, let me here exhibit to you the *regions* of the thorax, as they have been artificially mapped out for the purposes of auscultation.

It is unnecessary for me to describe particularly the method followed in this arbitrary division of the thorax into regions. I will state the names that have been commonly applied to them, and the sounds which in health they respectively yield, according to the numbers in the diagram before you.

The *first* region is that of the *clavicles*; one, of course, on each side. Upon these bones it is immaterial whether direct or mediate percussion be made. The sound given out should be very clear at their sternal extremities, dull at their humeral extremities, and clear at their middles. The resonance diminishes from the sternal towards the acromial end of the clavicle. These parts correspond to the summits of the lungs.

The *second* region is the *subclavian*. It lies between the clavicle and the fourth rib on each side. Beneath this superficial region lies the upper lobe of the lung; and towards the sternum large bronchi are situated. You will understand, therefore, that the sound educed by striking this part ought to be very clear.

A little lower down, number *three*, is the *mammary* region, extending from the fourth to the seventh rib on each side, and answering to the middle lobe of the lungs. Here also the resonance afforded by percussion is clear; but in the lower part of this region on the left side, we find the heart, which is more or less covered by lung: and on the right side the liver begins to mount. The sound is somewhat modified and deadened by these deeper-scated viscera. In women we can determine the degree of resonance of this region through the *mammæ*, by *mediate* percussion only.

[The annexed figure, borrowed from Dr. Hughes' work on Auscultation, will give the student a more clear idea of the several regions of the chest than the figures furnished by Dr. Watson.—C.]

FIG. 40.

1. Acromial regions, corresponding with the *eleventh* region of Dr. Watson.
2. The superior sternal region, corresponding with the *fifth* region of Dr. Watson.
3. The infra-clavicular regions, corresponding with the *second* of Dr. Watson.
4. The inferior sternal, corresponding with the *sixth* and *seventh* of Watson.
5. The mammary regions, corresponding with the *third* and *fourth* of Watson.
6. The axillary region (left), corresponding with the *eighth* of Watson.
7. The lateral region (left), corresponding with the *ninth* and *tenth* of Dr. Watson.
8. The scapular region (left), corresponding with the *twelfth* of Dr. Watson.
9. The infra-scapular region (left), corresponding with the *thirteenth* of Dr. Watson.

FIG. 41.

FIG. 42.

The *fourth* is the *infra-mammary* region. It comprehends that part of the bony compages of the thorax on each side which lies between the seventh rib and the edge of the cartilages of the false ribs. Into this region, on either side, may descend the thin anterior margins of the lower lobes of the lungs; but in the same region, on the right side, lies the liver, over which the sound of percussion is dull; and on the left side is placed the stomach. Hence when the stomach is tympanitic, a preternaturally resonant sound will proceed from this part; and when the stomach contains no gas, the sound will be irregularly dull.

All the regions hitherto described are double. There is still the mesial part of the front of the chest to be subdivided, and, we may call the three regions there situated, and numbered 5, 6, 7, the *upper sternal* region, the *middle sternal*, and the *lower sternal*. In all these the sound on percussion ought to be clear, except perhaps in the inferior portion of the last, which may be rather dull; or which, from its vicinity to the stomach, may be tympanitic.

The *eighth* region is the *axillary*; the axilla above the fourth rib on each side. The *ninth* is the *lateral* region, between the fourth and seventh ribs. In both these regions the resonance should be distinct and clear. The *tenth*, which may be called the *lower lateral* region, below the seventh rib at the sides, gives the same sounds as the *infra-mammary*, namely, on the right side, a dull sound, on the left a sound which at times is preternaturally hollow: on account of the presence of the liver in the former place, and of the stomach in the latter.

But we have yet to look at the hind part of the thorax. Here we have the space (region *eleven*) which forms the top of the shoulder, and lies between the clavicle in front, and the superior spine of the scapula behind: the *acromial* region. Very little can be made out by percussion in this spot; the sound is dull. But the depression immediately above the scapula, the *supra-supinal fossa*, as it is called, is a space which affords valuable information to the ear applied over it.

The *twelfth* region is the *scapular*. It comprises the part covered by the scapula on either side. It corresponds to the posterior part of the middle lobe of the lungs, but yields a dead sound, unless a pleximeter be used.

The *thirteenth* region is the *infra-scapular*. It lies between the inner edge of the scapula and the spine on each side. It corresponds to the roots of the lungs, and to the middle parts of their lower lobes. You may get a good clear sound here, if the patient's arms be crossed, and his head bent forwards, and his back arched, so as to stretch and tighten, and make as thin as possible, the superincumbent muscles; you will find also that the ridge of the spinal column in this part gives a hollow sound.

The last region to be mentioned, number *fourteen*, the *dorsal*, is the lowermost part

of the ribs behind. It answers to the base of the lungs, and gives a clear sound : but the liver on the right side is apt to render its inferior portion dull ; and the stomach on the left to make it unduly resonant.

Now, knowing these circumstances, if you find that a dull sound is yielded on percussing a part that should render a hollow sound, you conclude that beneath the part struck there is not the natural quantity of air. But whether this arises from consolidation of the lung itself, and the obliteration of its cells, or from fluid effused into the cavity of the pleura, you cannot, by mere percussion, determine. So, again, if the sound be unnaturally tympanitic, you cannot say whether that results from what is called pneumo-thorax, or from emphysema of the lung. Percussion testifies that air is there ; but further this deponent sayeth not.

The information which the exercise of percussion may leave thus imperfect, auscultation of the sounds produced by the acts of breathing, speaking, or coughing, will in most cases supply.

If the ear be laid close to the surface of a healthy thorax (or if the instrument called the stethoscope be interposed between that surface and the ear), the ear will hear the air enter and fill the lungs, and then withdraw and leave them again, in perpetual succession. The sound produced by this ingress and egress of air has been called the *respiratory murmur*. I might tell you that this sound, to my mind, is rather a rustle than a murmur : that it is like the sighing of the wind in the branches of a tree. I might say, with Laennec, that it resembles the sound made in the deep inspiration of a sleeping person ; or, with Mr. Davies, that it reminds one of the soft murmur of a pair of bellows, of which the valve does not click. But one minute's appliance of your ear to the subclavian region in a child, or even in an adult, will give you a clearer notion of the nature and character of this sound than any verbal description could convey. Yet, respecting this natural respiratory murmur, there are some things of which it is desirable that you should be previously informed.

In the first place, the *entrance* of the air is much more noisy than the *exit* ; which, sometimes, can scarcely be heard. You will see, by and by, the importance of noticing this fact.

In the next place, the murmur of respiration is not equally audible in all persons. It may differ much in intensity, though not in kind, in two persons, each of whom is in perfect health. Thus it is much more loud and distinct in children than in grown persons. So remarkably is this the case, that when we meet with an unusually noisy respiratory murmur in an adult, we say that his breathing is *puerile* ; it has the character of the respiration of a child. Now, I tell you beforehand, that puerile respiration in the lung of an adult is generally a sign of disease ; and it is mostly partial ; heard in certain parts only of the chest.

Again, *cæteris paribus*, the natural murmur of respiration is more clearly audible in lean and spare persons than in such as are muscular and fat. Fat and muscle are bad conductors of sound, and act as dampers. Listening to the breathing through a thick layer of adipous tissue, is like listening (as Dr. Latham says) to the respiration of a person through his clothes.

But if you take two healthy men who are alike in respect to leanness and fatness, you may often find that the respiratory murmur is very loud in the one, and very feeble, or almost inaudible, in the other : but in this last it *becomes* audible when he makes a deep and forced inspiration.

The reason of this difference is not very well understood. The breathing may be very indistinct, though the thorax be capacious, and well formed, and healthy. Some persons seem to require less effort than others to maintain the due equilibrium between the air in the lungs and the blood in the lungs ; as if they had not only pulmonary space enough, but to spare. So that the difference in the manner of breathing, and in the sound occasioned by the passage of the air in and out, depends, in all probability, upon individual peculiarities of the circulation. At any rate, it is very important that you should be aware of the existence of these differences.

But the sounds which reach the ear applied to the chest of a breathing person will differ in different parts, and under different circumstances. The sound given out by the air as it passes through the trachea and larger bronchi, differs from that which results from its passage into and out of the smaller bronchi and air-passages. I am anxious not to refine too much in these matters : and, therefore, I pass by

minuter points of difference. Place the stethoscope over the trachea, and you will hear just such a sound as you might expect to hear: the sound of air rushing through a tube of considerable size, a blowing noise. We will call that sound, which you will recognise again when you have once heard it, *bronchial* breathing. It accompanies the outward as well as the inward passage of the breath. Again, place your ear or your stethoscope upon the right mammary region: there you shall hear that rustling sound, which I propose to call *vesicular* breathing, and which is chiefly audible during inspiration. We shall find these distinctions of much use in the discrimination of disease. We shall find, for example, that the breathing sometimes is bronchial, where it *ought* to be vesicular.

Now if in any part of the chest where we should hear breathing, we can hear none, this may result from consolidation of the subjacent portion of lung; or from some obstacle in a large bronchus, preventing the air from entering that part; or from air being in any way shut up and stagnant in that part; or from an effusion of liquid into the pleura at that part. And here again percussio comes into play, and determines for us which of these possible circumstances is the one really present. If the part when struck emits a hollow sound, there is stagnant air beneath it, either in the healthy lung, or in the lung altered by disease, or in the cavity of the pleura. If a flat solid sound be given out, there is solid lung beneath, or liquid in the pleura, between the ear and the lung. All these points, and the conclusions to be deduced from them, will become clear to you, I trust, as we proceed. Minuter analysis of the diagnostic signs would be premature.

A word or two preliminary I must say about the *voice*.

The voice passes outwardly through the mouth and nostrils into the surrounding air; it passes also inwardly, through the trachea and bronchi into the lungs, and it may be heard through the lungs, by the ear laid flat against the chest. But it gives quite a different sensation to the ear in different places. If you place the stethoscope on the trachea, the voice will articulate itself into your ear as if it came from and through the instrument. This sound, which is natural here, would be unnatural, and a mark of disease, if heard beneath the clavicles. When heard beyond its natural situation, it is called *pectoriloquy*. A less degree of this, a sound like that of a person talking into a tube, and whose words, for that reason, are muffled and indistinct, is called bronchial voice, or *bronchophony*. When to this modification of the voice there is added a twanging vibration, a cracked discordant tremor, resembling the squeak of Punchinello, or (as some think) the bleating of a goat, *ægophony* is said to exist. All these unnatural modifications of the voice are indicative of most important changes within the thorax. I merely introduce them to you now: you will become better acquainted with them in due time.

It is a curious thing — of which I am unable to give you any satisfactory explanation, but which I had noticed a hundred times before I saw it mentioned in any book — that the resonance of the *listener's* voice, whose ear is applied to the patient's chest, is apt to be exalted or modified by certain conditions of the subjacent parts. I am not aware that any inference can be drawn from this phenomena beyond what other symptoms would still more readily and accurately supply.

What is true of the natural voice, is true, *mutatis mutandis*, of that unnatural vocal sound, *cough*. The cough may be so modified by the condition of the internal parts, as to reveal that condition.

There are yet other ways in which some information can be gathered respecting the interior of the chest. If you give certain patients a sudden smart jog while your ear is applied to their thorax, you may hear a splashing sound: like that produced by shaking a barrel or a bottle partly full of water. From this expedient you in fact determine that the cavity of the pleura, or perhaps a large excavation in the lung, does contain both air and a liquid. This is called the method of *succussion*. It was employed long before the other forms of auscultation were thought of. Hippocrates mentions it.

Again (but that is not auscultation), you may sometimes collect useful information respecting the state of the chest by simply laying your open hand upon it. In most persons there is a distinct vibration or thrill produced by their speaking, which thrill is very sensibly felt by the hand. Now this thrill may be felt on one side of the chest and not on the other. And such a difference is an unequivocal sign of disease.

The positions which I described before as being the most convenient for the performance of percussion, are the most convenient also for the purposes of auscultation. You may listen with the unassisted ear, or you may listen through the stethoscope. This, as you know, is a solid or perforated piece of wood, of which one end is adapted to the ear, and the other, which is to be applied to the chest, is hollowed out, or expanded, into the shape of a bell, or funnel. The object of the instrument is to collect and convey to the ear of the observer the vibrating impulse of the air, or of the solid walls of the thorax, occasioned by the motions within. The stethoscope is sometimes useful for examining a circumscribed spot in the thoracic cavity. With it we gauge, more nicely than we could do with the naked ear, the signs furnished by the patient's voice. We *must* use it also when we would investigate the breathing in parts to which the ear itself cannot easily be applied; and in cases where, from the filth of the patient, or because he has some infectious disorder, we desire to avoid any immediate contact with his clothes or person; and in cases of young or old ladies, to whose breasts it might not be seemly or delicate to be putting our faces. But, with these exceptions, the stethoscope, in my experience, is rather a hinderance than a help. Much, however, depends upon custom. I can best distinguish most of the sounds to be heard within the thorax by my unassisted—perhaps I should say my unimpeded—ear: and I therefore employ the stethoscope or cylinder in such cases only as I have just adverted to. I cannot do without the instrument, but I do without it as much as I can. Care should be taken that the end of the stethoscope next to the ear be closely and comfortably fitted to that organ; and that its other extremity be blunt, so as not to hurt the patient; and further, that it be uniformly and evenly applied to the surface of the chest. If these precautions be attended to, the shape and fashion of the instrument are very unimportant.

LECTURE XLVIII.

Catarrh; its varieties. Acute Bronchitis. Dry Sounds attending the Respiration; Rhonchus, and Sibilus: Moist Sounds; Large and Small Crepitation: how these are produced, and what they denote. Treatment of Acute Bronchitis. Collapse of the Lung—diffused, and lobular. Sudden Infarction of a large Bronchus. Peripneumonia Notha.

In the last Lecture I described to you, in a general manner, the method of auscultation; or the employment of the sense of hearing in the investigation of disease; and particularly of *thoracic* disease. I explained, as well as I could, the different sounds which result from percussing various parts of the chest; and from the entrance and exit of air during the several acts of breathing, speaking, and coughing. I mentioned certain conditions in which those natural sounds are abolished: but I did *not* speak, except incidentally and very cursorily, of the altered and new sounds to which the presence of disease within the thorax has been found to give rise. Nor do I propose to enter now upon any *formal* account of these morbid sounds. I shall endeavour to make you acquainted with their characters, and causes, and signification, as they arise in the progress of the separate thoracic diseases which I am about to consider.

Before you can possibly appreciate the *morbid* sounds, you must make yourselves familiar with the *natural and healthy*. You must have a standard, by which you may measure the numerous deviations from the natural sound, that will reach your ear in disease. Listen to the voice and the breathing of healthy children—or of some of your friends and fellow-students—and you will soon recognise those respiratory sounds which accompany the perfect state and working of the breath-machine.

I intend to commence with those diseases of the lungs in which the *mucous membrane* lining the air-passages is primarily or principally involved. This membrane is

often affected *alone*. It is much exposed to known *causes* of disease : to alternations of temperature in the air which is constantly passing over it ; to the irritation produced by acrid or noxious matters, solid or gaseous, which are mixed and inhaled *with* the air. And when disease commences in *other* parts of the lungs, it seldom fails to reach, sooner or later, the *mucous membrane*. In diseases also of the *heart* the same mucous membrane is very liable to be consecutively affected, by reason of those alterations in the condition of its capillary vessels which the disorder of the circulation produces.

Now I shall first point out the changes to which this mucous membrane is liable ; and then describe the modifications of the natural sounds that result from such changes ; and lastly, consider the different forms of disease which these changes constitute, and these altered sounds denote.

In a former part of the course I gave you some account of the peculiarities which differences of texture impress upon the phenomena and process of inflammation : and among the rest, I spoke of the behaviour of the *mucous* tissue when inflamed.

The mucous membranes, in the state of health, are perpetually *moist*. The exhalation of this moisture, to a certain amount, and *not beyond* a certain amount, constitutes an essential part of their healthy functions. Now their *inflammation* (for I am about to consider first the inflammatory affections of the membrane of the air-passages ; some of them indeed I have already discussed), I say the inflammation of these mucous surfaces alters their ordinary secretion. An inflamed mucous membrane is in the first instance *dry* ; its secretion is suspended. But this is not the only change that takes place in it ; it becomes tumid also, swollen, thicker than before : it is redder than natural : and its sensibility undergoes a perceptible modification. *Pain*, in mucous membranes, is *not* a common phenomenon : for their texture enables them to expand or dilate freely, so that they escape much tension, and the pain which is produced by tension ; but their natural sensations are blunted, and new and uneasy sensations arise in them : sensations of heat, fulness, itching. It happens that we can *see* a portion of the mucous membrane that belongs to the air-passages : and by noticing the changes produced in it by inflammation, we infer those which are apt to take place in the parts we *cannot* see. We have all often experienced in our own persons an inflammatory state of the membrane lining the nasal cavities ; the schneiderian membrane. At first the nostril is preternaturally dry : yet, though it is dry, you cannot breathe through it : it is stuffed up ; not with accumulated mucus, but by the mere swelling of the membrane : the sense of smell is perverted or lost ; the part is evidently red ; it is tender also and irritable ; the contact of atmospheric air a little colder or a little less pure than common, provokes sneezing. The affection extends often into the frontal sinuses ; and headache and oppression ensue : or it passes into and through the lacrymal sac, the conjunctiva participates in the inflammation, the puncta lacrymalia become impervious, and the tears flow over the cheek. And with all this there is sometimes shivering or chilliness ; and the pulse, especially in the evening, becomes a little more frequent than common. There is slight fever. After the unusual dryness, the membrane begins to secrete a thin serous fluid, having acrid properties : for it reddens and frets the *alæ nasi* and upper lip over which it flows. By degrees, this thin serous fluid becomes thicker, and as it becomes thicker it becomes less irritating also, more viscid, opaque, and yellow : the swelling of the membrane diminishes ; it is less raw and sensitive : at length the secretion resumes its natural *quality*, and is reduced to its natural *quantity* again ; and the tumefaction of the membrane entirely disappears. This is the course of what is popularly called a *cold in the head*. When the defluxion from the nasal membrane is considerable, systematic writers call the complaint *coryza* ; when it is attended with much pain and weight about the *frontal sinuses*, it is named *gravedo*. It is a variety of *catarrh*. In *catarrh*, sometimes one part, and sometimes the whole, of the mucous membrane of the air-passages suffers inflammation. If the disorder go down into the lungs, it is said to be a *cold in the chest* ; or, from one of the most prominent of its symptoms, a *cough* ; in medical language, *bronchitis*. It sometimes travels from one part of the membrane to another. Beginning, for example, in the nose, it gradually creeps down into the wind-pipe and lungs. Sometimes the inflammatory condition passes from the throat into the eustachian tubes, and produces deafness ; or down the gullet and to the stomach,

causing qualmish or other uneasy sensations, and loss of appetite. And occasionally this order appears to be reversed. There are some persons who will tell you that whenever anything disagrees with their stomachs, whenever dyspepsia is produced by some error in diet, they are sure to have catarrh.

Now I have adverted to this *cold in the head*, or *oryza*, because the phenomena which are open to our inspection in the sehneiderian membrane take place also, no doubt, in the bronchial. The membrane is first dry, and tumid, and irritable; the uneasy sensations of which it is the seat prompt to the action of coughing. The chest feels tight, stuffed, constricted. There is some hoarseness, and a sense of roughness and soreness in the wind-pipe; and a dry cough, which seems to arise from some irritation about the glottis. Sometimes, with these symptoms, pains in the limbs, like the pains of rheumatism, occur; the appetite is impaired; the patient is thirsty; and a general lassitude is felt all over the body.

But what effect has the altered state of the membrane upon the sounds elicited by percussion; or heard within the chest, by the ear, during respiration? Why it brings us acquainted at once with two remarkable modifications of the natural sound of breathing; and these I must describe and explain.

I will take this opportunity of again recommending you to read and study the lectures recently published by Dr. Latham. They contain a very plain and clear account of the auscultatory signs of disease within the chest; and he speaks of these signs in more easy and popular language, with less of over refinement, and a less subservient adoption of the French mode of thinking and writing on these subjects, than any other English author that I know of. I recommend his volumes the rather also, because he uses the nomenclature which is the most familiar to myself: in fact, as we some years ago saw and talked of these matters together in the wards of St. Bartholomew's, we were likely to employ the same terms.

When you listen, I repeat, to the breathing of a healthy person, you hear, as the breath goes in and out, but especially as it goes in, a smooth and gentle rustle—the *respiratory murmur*, or the *vesicular breathing*. But when the inner surface of the bronchial tubes, and of their ramifications, is preternaturally dry, and tumid, this sound is altered: you hear a hissing, or wheezing, or whistling, as the breath goes in and out; and this is technically called *sibilus*; or you hear a deeper note, a snoring noise, as the patient inspires or expires—a sound like the cooing of a pigeon, or the bass note of a violin, or the droning hum of an insect in its flight; and this is called *rhonchus*. These two, in their various modifications, constitute the *dry* sounds of respiration; and it will be worth while, once for all, to reflect upon their cause and nature, and the manner in which they are combined, and what they denote. You are aware that when air is driven through a cylindrical tube of a certain size, and when that tube is narrowed in a particular way at one or more points, a musical note is produced. Now this is what often happens in the larger bronchi; this is what *always* happens in them when *rhonchus* is present. Rhonchus belongs to the larger divisions of the bronchi exclusively; and as these are often, for a time, exclusively affected, so rhonchus may exist *alone*. It will be grave or deep in proportion to the length and diameter of the tube in which it is produced. When the sound is grave and deep, the hand placed upon the chest may frequently perceive a trembling or thrill communicated to its parietes. I believe that rhonchus is mostly occasioned by portions of viscid, half-solid mucus, which adhere to the membrane, and cause a virtual constriction of the air-tubes, and act as vibrating tongues while the air passes by them. I conclude such to be the case, because it seldom happens that the rhonchus cannot be got rid of by a vigorous cough. It will soon begin again, perhaps, or it will commence in some other part, but the effort of coughing, which detaches and removes the adhering tough mucus, dislodges also, for the time, the rhonchus. Yet, rhonchus in a given spot may be permanent: a tumour, or a tubercle, may flatten one of the air-tubes, and convert it into a musical instrument. For the most part, you will find what I have told you holds true: you may suspend the rhonchus by getting the patient to make a hearty cough. Now in the natural state of the chest, we do not, except in particular spots, hear the transit of the air through the larger bronchi. Whatever sound it makes is damped by the spongy lung, or covered by the vesicular breathing. But rhonchus, in its turn, may overpower the vesicular murmur, and render it inaudible. It does not prevent it, but it outroars it, as it were. Yet this

is seldom the case: you hear the rhonchus, and, if you listen attentively, you may in general hear, mingling with it, the vesicular murmur also. Recollect, then, that rhonchus belongs to the larger divisions of the air-tubes; that it denotes their partial narrowing; that it is a dry sound; and that the condition of which it is expressive implies usually no danger: there is no material obstacle to the passage of the air through these larger tubes into the vesicular structure beyond them.

I must further admonish you, that in your earlier essays in auscultation you will be apt to deceive yourselves in respect to the exact place in the lung in which the rhonchus which you hear is produced. It is so loud a sound, that when it proceeds from a single bronchial tube it may be plainly audible over the whole of that side of the chest; and sometimes, more obscurely, over the other side too.

When air is driven with a certain degree of velocity through a small pipe, it gives rise to a hissing noise. It is by forcing air through a cylinder perforated by a slender tube, that Professor Wheatstone obtains the sound of the letter S in the talking machine which he has constructed, after Kempelen's model. Precisely this condition we have in the smaller bronchial ramifications, when the inflammation in catarrh or bronchitis has reached *them*, and rendered the membrane lining *them* tumid. And sibilus is the result of this change. Now sibilus, like rhonchus, may exist alone; and, inasmuch as the sibilus proceeds from the smaller air-tubes, adjacent to the pulmonary vesicles, it *abolishes* the natural respiratory murmur. It does not, like simple rhonchus, merely drown it, but it takes its place. If you hear the respiratory murmur mingling with sibilus, you may be sure that some of the lesser air-tubes are narrowed, and some free: you cannot have both sounds at once from the same ramifications of the bronchi. Sibilus is a sound of more serious import, therefore, than rhonchus; it bespeaks a condition of greater danger. It belongs to the smaller air-tubes and vesicles, and denotes that they are in the first stage of inflammation, which has diminished their natural calibre, by rendering the membrane tumid. It is a dry sound, but you cannot cough it away.

I say rhonchus may occur alone, and sibilus may occur alone; but very often indeed they both occur together; and may be heard in various parts in different degrees: causing a strange medley of groaning, and cooing, and chirping, and whistling, and hissing, mixed, it may be, here and there, with the natural respiratory murmur. When you hear sibilus over the entire surface of the chest, the mucous membrane is universally affected, and the case is a severe one, and attended with considerable hazard.

It is just possible that a sibilant sound may proceed from a large air-tube, when its bore has been narrowed to a very minute slit or orifice; but this possibility does not interfere with the general distinctions that I have been endeavouring to point out.

Now in these cases we neither obtain nor require any information from percussion, except of a negative kind. Supposing the inflammation confined to the mucous membrane, the resonance on percussion will not be sensibly diminished; the lung is everywhere spongy still, and air reaches every part of it, though not with the usual freedom.

There is one exception to this. Occasionally, though rarely, a piece of tough phlegm may seal up, as it were, the very entrance of one of the principal bronchial tubes, and so prevent the air from passing to or from the portion of lung to which that tube conducts. When this happens, it is very likely to puzzle the auscultator for a time. There is air in the sealed-up portion of lung, therefore percussion gives a natural sound; but the air is at rest, therefore no sound of respiration is audible. An effort of coughing unstops, perhaps, the bronchial tube; and then the air is again heard to enter and to depart from that portion of lung. I shall advert to this sort of accident again.

Finally, I may remark, that these dry sounds, rhonchus and sibilus, are heard during the *breathing*; they have no relation to the voice or to the cough.

After a while, the inflamed membrane begins again to pour out fluid; but it is not the vaporous, bland, moderate exhalation of health; it is a glairy, saltish, transparent liquid, like white of egg somewhat; and if it be expelled only after much coughing, it will be frothy also, *i. e.*, it will contain many bubbles of air entangled in it. At first thin, and even watery, the fluid expectorated soon becomes stringy and tenacious, and the more so in proportion to the intensity of the inflammation. With this new condition of the membrane, we have new sounds—sounds which result from the

passage of air through a liquid; sounds which are occasioned by the formation and bursting, in rapid succession, of numerous little air-bubbles. These sounds are called *crepitations*. This process may take place in the larger air-tubes, or it may take place in the smaller, or in both. In the larger tubes the *bubbles* will be larger, and the ear can readily distinguish this; we have *large crepitation*. In the smaller air-tubes, we have, in the same way, *small crepitation*. There is no difference between these sounds, except in degree; and they graduate insensibly into each other. But there is a considerable difference in the nature of the intimations which their well-marked varieties convey. If there be merely large crepitation, without any other morbid sound, it is produced in the larger tubes. Air passes, notwithstanding, into the vesicular structure *beyond* the accumulated liquid; and vesicular breathing *exists*, though perhaps it *cannot be heard*, on account of the crepitation. But the state of the patient is not a state of peril. On the other hand, small crepitation has its seat in the smaller air-tubes and cells; it supercedes the vesicular breathing, and, if extensive, it bespeaks considerable danger.

Rhœchus and large crepitation are respectively the dry and moist sounds that belong to the larger bronchi; sibilus and small crepitation the dry and moist sounds of the smaller branches. When the latter sounds are heard over a considerable part of the chest, there is, I say, usually a good deal of distress, dyspnœa, and cough; and the fever which attends the local inflammation is at its height. By and by the expectoration becomes opaque, and more consistent, and of a greenish or yellowish colour; it is brought up with more ease; the crepitation, great and small, diminishes; perhaps rhœchus reappears: but at last the parts return to their original condition; and the natural, smooth, equable rustle of the breathing is again everywhere audible.

These are all the morbid sounds to which active and recent inflammation of the mucous membrane of the air-passages ever gives rise: rhœchus and sibilus; large and small crepitation. Having once described their nature and causes, I need not repeat the description if we find them accompanying other diseases; but their *import* may be different. I may mention here, that as crepitation results from the passage of air amongst and through a liquid, from the rupture of the little air-bubbles so produced, the *kind* of liquid may vary. If the air in going and returning, meet with serum, or with pus, or with blood, it will occasion exactly the same bubbling noise. Hence the French term for what I have been calling crepitation, viz., *mucous rattle*, is very objectionable. From the sound itself, we cannot tell whether it proceeds from *mucus* or from some other liquid present in the air-passages; and from this objection the word crepitation, whatever exception may be taken against it on other accounts, is free.

Having thus embraced the occasion of explaining these auscultatory signs, I will now resume the history of catarrh. It implies inflammation of the mucous membrane of the air-passages; and it receives different appellations, according to the district of that membrane which it chiefly plagues: gravedo, in the frontal sinuses; coryza, in the schneiderian membrane of the nose; bronchitis in the trachea and lungs.

Catarrh is the commonest of all disorders. Not one man in ten thousand passes a winter without having a *cold* of some sort. And this name points to its ordinary cause: cold somehow applied to the body. It does not always or often result, I apprehend, from cold air brought into contact with the membrane itself, in the process of breathing; but from cold, and especially from cold and wet, applied to the external integument. It is unnecessary for me again to go over the circumstances under which the application of cold is most likely to prove injurious. Catarrh is usually a trivial disorder, and runs its course in a few days, if abstinence be observed with respect to animal food and stimulating liquor, and if the patient remain in an equable temperature, and avoid re-exposure to the cause of his malady. I am now speaking of the milder forms of catarrh. We are not often consulted for this complaint. Every man, in regard to a cold, thinks himself qualified to be his own doctor. But if you are consulted, keep your patient in the house, or even in bed; let him live upon slops; give him a gentle aperient, and then some of those medicines which are esteemed to be diaphoretic: small doses of James's powder; three drachms of the liquor ammoniæ acetatis, with a drachm of the spiritus ætheris nitrici, and an ounce of camphor mixture; or a saline draught with an excess of alkali, and a few grains of nitre, or a little antimonial wine; give some such dose three or four times a day; and let him

take four or five grains of Dover's powder, and put his feet and legs into a warm bath, just before he goes to bed. In this way you may conduce to his *recovery*; and he may be simple enough to suppose that you have *cured* him.

Yet I believe catarrhs *may* sometimes be *cured*; and the natural recovery from them *may* be, *sometimes*, accelerated. If you practise the old maxim, which says, "*venienti occurrere morbo*," you may occasionally stop a cold on the threshold, as it were by an opiate. And to persons who are habitually troubled with slight catarrhs, this piece of practice may prove of the greatest value. A surgeon who resides in this neighbourhood, and with whom I was a fellow-student, is exceedingly subject to what he calls a snivelling cold. For many years he used to bear this as he best might; and that, to say the truth, was very ill and impatiently. On one occasion, almost by accident, he took twenty drops of laudanum just as one of his colds was beginning to torment him; and he found that the initiatory symptoms vanished. Since that time he has constantly had recourse to the opiate under similar circumstances; and whereas he used formerly to be very miserable for three or four days, he is now quite well and comfortable in the course of half an hour. And this is not a solitary ease. It is worth trying, if you experience the feelings of an incipient catarrh, to go to bed, and to take a beaker of hot wine negus, with a tablespoonful of the syrup of poppies in it. This will not suit every person, but if it fail on the first trial, it need not be repeated, and no great harm, beyond an increase of headache, can be done by it. I would not recommend this plan, however, to a plethoric person; nor to any one having a tendency to inflammatory disease; for when it does not cure, it makes the complaint worse.

There is also a period in catarrh which has gone on unchecked, when you may accelerate its departure—"speed the going guest"—by a good dinner; and an extra glass or two of wine. But this pleasant method is scarcely to be advised for persons of delicate habit; or in whom any phthisical tendency is suspected to exist; or who are prone to inflammation. And it is not to be tried with any one till the fever is over, and expectoration thick and loose.

I must not omit to mention the *dry* plan of cure; although (I confess it with some shame) I have never yet tried it either upon myself or upon others. Dr. C. J. B. Williams, who invented it I believe, has a high opinion of its efficacy. It certainly has the merit of simplicity, for it consists merely in abstinence from every kind of drink. No liquid, or next to none, is to be swallowed until the disorder is gone. The principle here concerned is that of cutting off the supply of watery materials to the blood. The wants of the system exhaust, from the circulating fluid, all that can be spared for the natural evacuations; and there is nothing left to feed the unnatural secretion from the inflamed mucous membrane. Its capillary vessels cease to be congested; the morbid flux is diverted, and the inflammation starved away. Such is the theory. Habitual toppers might hold the remedy to be worse than the disease; but Dr. Williams assures us that the necessary privation is not very hard to bear: and that it achieves a cure, upon an average, in forty-eight hours. He allows, without recommending, a tablespoonful of tea or milk for the morning and evening meals, and a wine-glass of water at bed-time.

One great advantage of this plan is, that it does not require confinement to bed, or to the house. The man whose business calls him abroad, may, with appropriate clothing, pursue his customary employment, and his cure is all the while going on. In fact, exercise, inasmuch as it promotes perspiration, helps the recovery; whereas the system of warm drinks and diaphoretics renders the body more susceptible to atmospheric vicissitudes; and, to be effectual, implies restrictions which are oftentimes extremely inconvenient.

Dr. Williams observes, that while this dry treatment is serviceable in catarrhal bronchitis, it is *most* successful in coryza, snivelling cold in the head. It must be put in force in the very commencement of the disorder.

You may often do much by way of *prevention*, for persons who are unusually liable to take colds. I have remarked before upon the great value of the *shower-bath* for that purpose. I could mention several instances in which persons have got rid of the tendency to catch cold by the habitual use of this aspersion. It should be begun in the summer, and the water should at first be tepid; but in a short time quite cold water may be employed; and being once begun, the practice may be continued

throughout the winter. I stated formerly, that the effect of exposure to cold was, *cæteris paribus*, in proportion to the intensity and the duration of the sensation of cold that it produced. The intensity of the sensation of cold under the shower-bath is considerable, but the duration of it is momentary. It operates as a prophylactic in this way: it inures the surface to a lower temperature than it is likely to be subjected to at any other part of the day. The lesser degrees of cold have then no injurious effect, unless they are long protracted. For those who cannot procure a shower-bath, or who cannot bear its shock, cold sponging will be found exceedingly salutary.

But inflammation of the membrane lining the air-passages may be, and often is, a very acute and dangerous disorder, *i. e.*, the inflammation may be both intense and diffused; it may descend into the vesicular texture, and occupy the whole surface of the membrane on one side of the chest, and then it may prove a very grave disease; or it may involve the whole lining membrane of both lungs, and then it is always attended with considerable peril.

This inflammation will sometimes, when it is thus *general* over the whole membrane, linger for a considerable period in its first stage; and it may even, after so lingering, subside again without ever passing beyond the first stage. By the first stage, I mean the stage of dryness. Very little notice of this modification of bronchitis has been taken by authors. Dr. Latham has given a distinct and graphic description of it, to the accuracy of which I can testify from my own experience. You will find cases of it detailed in his book. Since they were published, some striking instances of this form of the disease have occurred to myself. One, which happened lately, I will relate by way of example. I was asked by an old pupil of the hospital to see a lady, his patient, in Gordon Square. I found her feverish, and in a state of extreme dyspnoea, sitting up in bed from inability to lie down, labouring for breath; her face turgid and rather livid, her nostrils working, her shoulders elevated. She could scarcely speak, but expressed, in what she did say, a dread of immediate suffocation. She had been in nearly the same state for a day or two. On listening at her back I could hear the air slowly wheezing and whistling into her lungs everywhere, and then leaving them still more slowly, with a prolonged growl, something like that of an angry cat. There was no true vesicular breathing; there was no crepitation: and there was no part into which the air did not, although with difficulty, find its way. The chest was everywhere resonant on percussion. There could be no doubt that the membrane throughout was tumid and dry, and in the earliest stage of inflammation. Depletion had already been employed in this case, and we had recourse to the tartar emetic. This was given in free and repeated doses, till it produced nausea and sickness. Whenever it did so, the pulse diminished in force, the face became blanched, and the breathing much easier; and the medicine was then suspended until these effects had gone off, when it was repeated in the same manner. The disease was not, however, brought at once to an end by this treatment; it was kept at bay for a day or two longer, and then a copious secretion from the membrane took place, with great relief to all the distressing symptoms. Then, of course, crepitation became universally audible. Except the debility which it left behind, the patient soon recovered of the bronchial inflammation.

But in the great majority of instances the inflammation does not thus linger in its first stage: the membrane soon begins to pour forth glairy mucus; so that we do not often meet with *sibilus*, without finding at the same time, in some part of the same lung, that there is also small and large crepitation. It is of some importance to attend to the characters of the mucus that is expectorated. It is transparent and adhesive. If you pour it from one vessel into another, it flows out in one mass of extreme tenacity; it will draw out sometimes like melted glass; and the degree of viscosity is a tolerably accurate measure of the degree of the existing inflammation. Upon the surface of the viscid mucus there is usually more or less froth, the *quantity* of it depending on the facility or the difficulty with which the sputa are brought up. If the patient do not expectorate till after a long fit of coughing, during which air has been many times inspired and expired, and has thus got intimately mingled with the mucus that fills the air-passages, the expectoration will contain numerous little air-bubbles; will be very frothy. Sometimes also, during this stage of the complaint, the sputa are marked with streaks of blood.

While the expectoration possesses the characters I have been describing, the in-

flammation is still active, and the fever and dyspnoea considerable. This correspondence between the general symptoms and the matters spat up was well known to the ancients, who said that such expectoration was still *crude*. But in proportion as the inflammation approaches to resolution, the appearance and qualities of the sputa are changed: the mucus loses by degrees its transparency, is mixed with masses or pellets that are opaque, and of a yellow, white, or greenish colour: and these masses, few at first, increase more and more in number, until they constitute the whole of the sputa. Such expectoration as this is commonly accompanied by a marked remission in the different symptoms of the bronchial inflammation: it announces that the inflammation is terminating in resolution. It is such as the ancients spoke of as being *concocted*, or *ripe*. However, the characters of the opaque sputa expectorated towards the end of an attack of acute bronchitis are subject to much variety.

It will often happen that the expectoration after having thus become opaque, and parti-coloured, will go back again to its former condition of transparency, and stickiness, and froth: and that is a very certain index of a return or increase or extension of the inflammation; so that the character of the matter expectorated exhibits, in a certain degree, the progress of the inflammation; and consequently constitutes one point of guidance to our treatment. The nature of the expectoration forms also an important particular in our means of distinguishing bronchitis from pneumonia; as I shall further explain when I speak of the latter disease.

I have described acute bronchitis as it appears when it terminates favourably: in such cases the inflammation generally begins to abate somewhere from the fourth to the eighth day of the disease. But acute bronchitis may terminate *unfavourably*. When the inflammation is universal and intense, the fever high, and the labour of respiration great—if the symptoms do not yield to the treatment employed, or if judicious treatment have not been adopted, or have been too long delayed, signs of impending suffocation begin to show themselves: the lips, and cheeks, and tongue, assume a purplish colour; a livid paleness takes the place of the former red flush; the expression becomes more and more anxious; delirium comes on, and rapid sinking. These indicate, you know, the circulation of blood that is in a great measure venous through the arteries; and the venous blood acts as a poison when it so circulates. Profuse, cold, clammy sweats ensue; and the patient dies of apnoea. His breathing is choked by the morbid secretion which occupies the bronchial tubes, small as well as large, and which he has not strength enough left to cough up.

FIG. 43.

Injection and stasis in the vessels of the bronchial mucous membrane, in bronchitis, seen by a low power. The vessels were disposed in longitudinal clusters, united by transverse inosculations.

Accordingly, when we examine the thorax after death so produced, we find, in the first place, that the lungs do not subside upon the admission of the pressure of the atmosphere to their external surface. We next find the trachea, and bronchi, and their ramifications, blocked up by a frothy adhesive mucus, resembling that which during life had been expectorated: and the membrane which lines them is red and thickened.

The treatment proper for these acute and dangerous forms of bronchitis is a matter of some nicety. Blood-letting, as I formerly stated to you, has not that decided power over inflammation of *mucous* tissues which it possesses over the adhesive inflammation to which serous membranes are liable. Nevertheless, if there be much fever, a hard pulse, and great oppression of the breathing, and particularly if these symptoms present themselves in a young, strong, and robust individual, it will be proper to take away blood. And you will always find blood-letting *relieve* the symptoms; even when its ultimate effect may

be injurious. The patient's distress arises from his inability to supply air enough to arterialize the venous blood which is carried to his lungs; and by diminishing the quantity of blood in those organs, you will, *pro tanto*, mitigate his uneasiness. But a great part of the danger to be apprehended in the advanced periods of the disease, is that the patient may not have muscular power enough to disembarass his air-

passages of the phlegm that overloads them; to draw a strong breath, and to achieve a vigorous cough. And this danger must be borne in mind in our earlier curative efforts. After much thought and observation, I have come to the conclusion that in these cases it is more safe, and not less effectual, to take blood from the surface of the chest by cupping, than to open a vein in the arm. The space between the scapulae is the most eligible spot for the application of the cupping-glasses; but they may also be placed upon the front of the thorax. The amount of blood to be thus abstracted, and the question of repeating the cupping, must be determined by the condition of the patient's pulse, which supplies a better measure of the propriety of depletion than is furnished by the local symptoms.

After the bowels have been cleared by a mercurial purgative, calomel and jalap for example, you will find the tartar emetic a very valuable medicine in these acute cases of bronchitis. It should be given in such doses as will excite nausea, and if vomiting be occasioned, you may still go on with the medicine after the sickness has subsided. The depression which this substance produces is great, but it is temporary, and it is effected without expending blood. With the antimony—I mean during the same period—mercury may and ought to be given: to this combination I should be inclined to trust more than to any other internal treatment.

If symptoms of debility and sinking have begun to show themselves, it will be necessary to administer stimulating expectorants. I presume that the carbonate of ammonia, which is often extremely useful in such cases, acts as an expectorant, by giving a fillip to the muscular power. But it is supposed by some persons to exercise some specific influence upon the bronchial membrane. However this may be, five or six grains of it, given in solution every four or six hours, are often followed by free expectoration and a marked improvement.

One of the circumstances of which patients are much disposed to complain, is the violent or importunate cough; and another is, the want of sleep and of rest: indeed the one of these is often, in a great measure, the cause of the other:—the urgency or frequency of the cough prevents the patient from sleeping. Now there is nothing so well calculated to allay cough, and to procure sleep, as opium; and you will be strongly tempted to give these patients opiates, and you will probably be encouraged to do so by the success which will follow that practice in many cases. The good effects of a full narcotic at bed-time are sometimes very striking. Patients who for previous nights have been perpetually harassed by cough, and who are worn out by the disturbance of their rest, will sleep tranquilly, and in the morning expectorate largely and freely, and declare themselves wonderfully the better for their opiate. Yet opium is a ticklish remedy in these cases. Many a patient—some within my own knowledge—labouring under general or extensive bronchitis, have been put so soundly to sleep by a dose of opium on going to bed, that they have not waked again. I believe you may receive it as a golden rule, not to give opium—I mean in a full dose, so as to force sleep,—if you see any venous blood mingling in the general circulation,—if the complexion be dusky, and the lips in any degree blue. The circulation of half-arterialized blood through the brain is in itself a powerful cause of coma; and if you add the influence of an opiate, the coma may easily be made fatal. While the cheeks and lips remain florid, and when the first violence of the disease has abated, an opiate will do capital service. It is a common practice to combine it with antimony or some other expectorant. Twenty minims of laudanum, with the same quantity of the *vinum antimonii potassio-tartratis*; or a third of a grain of the acetate of morphia, with a drachm of oxymel of squills; are convenient forms.

Counter-irritation is frequently of great use, as an auxiliary measure, in the treatment of acute bronchitis. Sensible relief of the cough, and of the oppressed breathing, often follows the rising of a large blister laid across the front of the chest. When the dyspnoea is extreme, and a more speedy counter-irritant is required, you may have recourse to the mustard poultice. Inhalation of the steam of hot water is also very soothing and useful. It is one of the best expectorants I know of, when it answers at all; but to some persons it proves irritating, and they derive no comfort from it.

I have been speaking of acute bronchitis, uncombined with any other pulmonary disease; and it is curious how little disposed the inflammation often seems to be to extend itself from the mucous membrane to the neighbouring tissues. The reason, doubtless, is, that this membrane is furnished with a distinct set of blood-vessels, the

bronchial arteries, and veins: while the substance of the lungs is supplied by the pulmonary. We could not tell, merely by attending to the general symptoms, whether the inflammation was limited to the inner membrane or not; but by making use of the sense of hearing, we are able to determine this. If the inflammation should spread to the parenchymatous texture of the lungs—*i. e.* if the bronchitis should pass into pneumonia,—this circumstance would be disclosed by physical signs, which I shall in due time describe and explain; and it would demand certain modifications of our plan of treatment.

In the later stages of acute bronchitis, and in various disorders of the bronchial membrane, a peculiar condition of the lung is apt to result, mechanically, from obstruction of the air-tubes by inspissated mucus. This condition is one of great pathological interest; but it was not recognised, or if recognised it was not clearly understood, till of late years. It has been well described and explained by some modern French and German writers. The best English accounts of it to which I can refer you are those of Dr. William Gairdner, as it occurs in the bronchitis of adult life—of Dr. West, as it is modified somewhat in the lungs of children—and of Dr. Alderson, in its connexion with whooping-cough.

The condition of which I speak is that in which portions of the lungs are completely exhausted of air. Naturally, you know, the healthy lung contains a residual quantity of air even after the most forcible act of expiration. When taken from the body the healthy lung is moist, has a spongy elastic feel, and crackles slightly under pressure. But through the operation of disease, portions of the living pulmonary tissue may become as thoroughly devoid of air, as the whole of that tissue is in infants who have never breathed. Those empty portions are firm, tough, dry, of a dull red colour, and they sink when placed in water. The surface exposed by their section looks to the naked eye like a piece of muscle. Hence they are sometimes said to have become *carnified*. This state has been confounded with, but is very different from, a morbid state that I shall soon have to describe, in which the lung, from its resemblance in texture to liver, is said to be *hepatized*; in which there is the same dull red colour, and the same absence of crepitation under pressure, but the affected tissue is friable, and its cut surface moist and granular. In the one case the air cells are empty; in the other they are choked up with the exudations proper to inflammation: in neither case do they contain air.

This empty condition of the pulmonary substance may result from the expulsion of the air by pressure from without: as when the lung is pushed firmly against the ribs and vertebral column in pleurisy attended with liquid effusion—to be described hereafter. The lung thus compressed and looking like flesh has been not unaptly called *carnified lung*. But the cause of the absence of air is more often internal, and consists in the plugging up of one or more air tubes; and then *collapse* of the lung is said to have taken place: and this is the more common and the more correct term.

The mechanism of this collapse is very simple and intelligible. Small portions of tough and sticky mucus are driven to and fro in the larger air tubes during the alternate acts of respiration, or in the paroxysms of a cough. Mostly they are expelled by the cough which their presence provokes. But it may happen, and it often does happen, that during inspiration one of these pellets, forced strongly backwards in a tube which gradually becomes smaller and smaller, shuts up that tube, and all the smaller branches that proceed from it beyond the place of the obstruction. In expiration the plug moves a little outwards again, so as to allow a part of the imprisoned air to escape; but returning in inspiration, it does not permit any fresh air to enter. Repetitions of this process exhaust, or nearly exhaust the air from the portion of lung thus mechanically sealed up. The portion so exhausted suffers collapse.

Collapse of the lung may be *diffused*, or *lobular*.

In the first of these forms, which is also the most common of the two, the collapse extends over a considerable portion of one lung, or of both lungs. The collapse may not be complete, nor the absence of air total. The affected piece of lung may still therefore float in water. Its colour, which varies according to the quantity of blood contained in it, is usually a dark, brownish red, gradually shading off sometimes into the hue of the adjoining lung. This diffused collapse is generally met with in the posterior parts of the lungs.

The second, or lobular form of collapse, is more sharply defined, and its well-marked

outline strikes the eye at once. The affected lobules, or bunches of lobules, occupy the anterior edges of the lungs, as well as other situations. They are slightly depressed below the general surface of the lung. Seen through the pleura, they have a dark red or violet colour; and when cut into they present a brown or mahogany hue. This form of collapse occurs chiefly in the lungs of children, and it was formerly regarded as the consequence and evidence of lobular pneumonia. The condensation is not due, however, to present or to by-gone inflammation, but simply to the absence of air. When the change is of recent date, the collapsed portions may be restored to their natural volume and condition, by blowing air into them through their proper bronchial tubes.

When collapse has taken place to any considerable extent during an attack of bronchitis, the breathing is apt to become laborious. The act of inspiration is performed with effort, difficulty, and distress; while that of expiration is comparatively easy. The patient is unable to lie down. All the muscles accessory to the inspiratory movements are called into play, yet little air finds entrance. Dr. Gairdner speaks of this "long-drawn, exhausting, inadequate inspiration, as being probably peculiar to obstructive bronchitis." The paroxysms of severe dyspnoea incidental to bronchial disorders are doubtless often owing to casual changes in the position of portions of tenacious mucus in the air tubes.

You will bear in mind this condition of collapse, and the laboured respiration associated with it; for I shall have to point out to you a striking contrast, in respect to the manner of breathing, when we come to the consideration of pure pneumonia.

Collapse of the lung, in proportion to its extent and its proximity to the surface, must modify, and in some degree lessen, the resonance of the chest under percussion. When such modification of the stroke-sound springs up in the course of an attack of bronchitis, and the patient's respiration becomes at the same time laborious, these conjoint symptoms will generally suffice to reveal the presence and the character of what may be called an accident of the disease. From this accident, when it is recent and uncomplicated, both reason and observation teach us to believe that the lung may recover, upon the removal of the obstruction, and the consequent readmission of air. And it seems probable, as Dr. Gairdner has suggested, that the muscular contractions of the bronchial tubes themselves have frequently a greater share than the movements of respiration, in promoting the expulsion of the accumulated mucus.

A similar accident may sometimes convert an apparently slight attack of bronchitis into a most perilous and quickly fatal malady. A large plug of tenacious mucus may all at once enter and stop up the principal bronchus of one, or of the other lung. Sudden and urgent dyspnoea ensues, and unless the plug be dislodged, the patient may perish before any collapse can be effected. Instantly, in that portion of the lung to which the bronchus conducts, all sound of respiration ceases: yet over this same portion of lung, in which no sound, healthy or morbid, is heard by the ear applied to the thorax, percussion gives the natural hollow sound. If the obstructive mass be fortunately expelled, or displaced, in the desperate struggle for breath, the sound of respiration is re-established as suddenly as it had previously disappeared: and the dyspnoea also ceases. In some cases, however, the noise of the pulmonary expansion does not so return, the difficulty of breathing increases, suffocation becomes imminent, and death by apnoea takes place rapidly.

Andral relates two instances of death from this cause; one of which was the following. A coachman, fifty years old, had been several times a patient in La Charité, for obstinate pulmonary catarrh, with slight dyspnoea, and puriform expectoration. Every time he went away relieved, but not cured. On both sides of his chest could be heard all the varieties of rhonchus. In one spot the column of air which penetrated the bronchi imitated the snoring of one in a deep sleep; in another spot it was like a dull and prolonged groan; in a third, a sound resembling that made by bellows, and in a fourth the cooing of a turtle-dove, were exactly simulated. On the last occasion of his entering the hospital, his respiration was still tolerably free. One morning he was found in a state of unusual anxiety. In the middle of the night, after a violent paroxysm of cough, his breathing (he said) had suddenly become very much oppressed. It was discovered, on auscultation of his chest, that no air penetrated into the upper lobe of the right lung; yet that part sounded well on percus-

sion, even louder than the corresponding part of the other side, which was morbidly dull. The difficulty of breathing went on augmenting, and the man was soon dead.

Besides other marks of disease in the lungs, the primary bronchus leading to the upper lobe on the right side was closed up completely by tough mucus, and exhibited the appearance of a full cylinder.

In the other case, also, the obstructed bronchial tube supplied the upper lobe of the right lung.

It may seem strange that the interruption of the access of air to so small a portion of the lungs should be attended with such serious consequences, when we know that the greater part of each lung may be impermeable by air, and yet the patient live a long time, and often without any great dyspnœa. The explanation of the apparent difficulty seems to be, that in the one case the prevention of the arrival of air in the part affected is sudden, in the other gradual. Moreover, the remaining portions of the lungs are performing their functions imperfectly.

When once attention has been awakened to the kind of accident just mentioned, the diagnosis would not seem to be difficult. We may suspect obstruction of one of the bronchi when considerable dyspnœa comes on suddenly during the continuance of simple bronchitis: and our suspicion will be confirmed if at the same time respiration ceases to be audible in a certain portion of the lung, while the sound given by percussion over the same part remains unaltered. Emphysema of the lung (which I shall explain hereafter) is the only other condition which could give rise to similar physical signs.

Andral judiciously suggests the employment of emetics, and the inhalation of steam, in such cases.

I shall have to speak of some varieties of chronic bronchitis; but there is a mixed form of pulmonary disease that requires to be noticed, in which acute or subacute inflammation engrafts itself upon changes that are chronic and abiding. Sydenham calls the disorder to which I now refer *peripneumonia notha*—bastard peripneumony. *Catarrhus senilis* is another of its names. It may be considered as chronic bronchitis, occurring in old persons, and very apt to be converted into pneumonia, or to be greatly aggravated in degree during winter, or upon any accidental exposure. This is the common complaint of persons advanced in life. I mention it here in compliance with the usual custom, and because this is as convenient a place for its introduction as any. But it would be an error to regard it as exclusively a disease of the mucous membrane of the lungs. An habitually congested state of that membrane, marked by some shortness of breath, and some expectoration, and by the constant presence of some degree of crepitation in the lower parts of the lungs,—these are circumstances which are of daily occurrence as consequences of *disease of the heart*; and it is in persons whose habitual health is of this kind, that what is called *peripneumonia notha*, which implies a diffused inflammation of the pulmonary mucous membrane, with sometimes an enormous secretion from its surface, is most apt to supervene. Almost all such persons will tell you that there are periods at which they experience slight febrile attacks, and exacerbations of their complaints: they have pain in the breast or side, headache, heat, and thirst; and at these periods the cough and expectoration are always aggravated, and continue for some time to be more than commonly severe. “The disease (says Cullen, who, following Sydenham, has given a good description of its general symptoms) has often the appearance only of a more violent catarrh; and after the employment of some remedies, is entirely relieved by a free and copious expectoration. In other cases, however, the feverish and catarrhal symptoms are at first very moderate, and even slight; but after a few days these symptoms suddenly become considerable, and put an end to the patient’s life, when the indications of danger were before very little evident.”

The truth is (and we learn the truth by the evidence of auscultation), that in these cases *pneumonic* inflammation is often suddenly set up. There is no security, as Dr. Latham observes, that the portions of lung which yield crepitation to-day may not be solid and impervious to-morrow. Dr. Latham is of opinion that in this disease the inflammation is apt to travel over the bronchial membrane from place to place, as erysipelas is seen sometimes to wander over the surface of the body. I know not how this may be; but certainly death is often produced in these persons by the sudden

spoiling of even a moderate portion of lung; or by its sudden *closure*. For it is more than probable that, in many of these cases, the distressful symptoms result (especially when they bear no inflammatory character) from the rapid accession of pulmonary collapse. In their ordinary condition, the patients have just enough, and no more, of the respiratory apparatus in an effective state, whereby to subsist; and when a fresh part of it is rapidly rendered solid and useless, they quickly perish. But they die also from another cause. The nicety of treatment which I spoke of as being required in certain stages of acute bronchitis, is still more apparent and necessary here. We are placed in this dilemma. If we do not take blood in the inflammatory attacks, we run a risk of losing our patient from the effects of the unchecked inflammation; and if we do bleed, we are in danger of losing him by producing a degree of weakness which will render him unable to expectorate the effused mucus, and so liable to perish by suffocation. Cupping and blisters are the remedies most suitable when there is evidence of recent inflammation — what are called expectorants and perhaps emetics, when we have reason to suspect collapse. Medicines which are at the same time diuretic are also serviceable — the spiritus ætheris nitrici, the preparations of squill, and of digitalis.

LECTURE XLIX.

Influenza. Symptoms and progress. Conjectures as to its cause. Treatment. Hay asthma. Chronic Bronchitis. Its varieties. Morbid anatomy of these affections. Dilatation of the Bronchi.

CATARRH, which was the principal subject of the last lecture, occasionally prevails far and wide as an epidemic disease. I speak, indeed (February 4, 1837), during the immediate presence of one such visitation, although the extreme violence of the complaint that has been raging among us is now fast subsiding. You can hardly be without curiosity to know what has been learned respecting an influence which has thus, on a sudden, before your eyes, disturbed and sickened a whole community. I have here used, without thinking of it, the very word by which, in a foreign version, the disorder is denominated. It has received, however, various names; for it has been known and noticed from remote antiquity. Cullen calls it *catarrhus e contagio*: and under that head, in his *Nosology*, you will find a copious reference to recorded accounts of epidemic catarrh, as it has been observed to spread over great portions of the world. In France the disorder thus prevailing, is styled the *grippe*. The Italians, putting the cause for the effect, call it *influenza*, the *influence*: and this last term influenza has now become naturalized in our language. Since Cullen wrote there have been four or five more of these epidemics. One in 1782, which extended over all Europe, visiting every country therein, affecting more than one-half of its inhabitants, and proving fatal to very many of them. You will find, in the third volume of the *Transactions of the College of Physicians*, a good account of the disease as it then showed itself in this country. In the spring of 1803 another instance of it occurred; and of this the history, as compiled from the testimony of a hundred and twenty-four observers, is preserved in the ninth and tenth volumes of the *London Medical and Physical Journal*. In the month of April, in the year 1833, the influenza again made its appearance, and prevailed extensively, both here and elsewhere. and of the influenza of 1837 you have had, and you still have, the opportunity of being observers. A very good and instructive sketch of this epidemic malady, compiled by Dr. Hancock, is to be found in the *Cyclopædia of Practical Medicine*. To that article, to the publications I just now mentioned, and to the works enumerated by Cullen, I may refer you for much which is curious and interesting in the history of the disease; but which would not be so well adapted to our immediate purpose in this place — namely, that of seizing upon the practical facts which have been ascertained respecting influenza.

One characteristic feature of this species of catarrh, as distinguished from the ordinary sporadic disorder, is the sudden occurrence, in the outset, of more decided febrile disturbance. The first two patients whom I saw in the epidemic of 1833 had just the symptoms which frequently mark the commencement of an attack of continued fever; and I did not know, at my first visit, what was about to happen to them. The symptoms, taking them altogether, are somewhat as follows. The patient is chilly, and perhaps shivers; presently headache occurs, and a sense of tightness across the forehead, in the situation of the frontal sinuses; the eyes become tender and watery; and sneezing and a copious acrid defluxion from the nose ensue, followed or accompanied by heat and uneasiness about the throat, hoarseness, a troublesome cough, and oppression of the breathing. In short, the symptoms are the symptoms of catarrh; including in that term all the varieties thereof that are sometimes met with separately—*gravedo*, *coryza*, *bronchitis*: and with these symptoms, a sudden, early, and extraordinary subdual of the strength; and, most commonly, great depression of spirits. The debility which comes on at the very outset of the complaint is one of its most singular phenomena, taking place, in some cases, almost instantly, and in a much greater degree than would seem proportioned to the other symptoms of the malady which it thus ushers in. Indeed, this rapid and remarkable prostration of strength is more essentially a part of the disorder than the catarrhal affection, which sometimes (though rarely), is absent, or imperceptible. It is upon the mucous membranes, however, that the stress of the disease generally falls; especially upon the internal lining of the air-passages. Those of the alimentary canal seldom escape entirely; but they suffer in a less degree. The tongue is white and creamy, the palate loses its sensibility, the appetite fails, nausea and vomiting are not uncommon, and sometimes there is diarrhœa. The pulse, in the uncomplicated disease, is soft, and generally weak. The skin, at first hot and dry, soon becomes moist, and sometimes exhales a peculiar musty smell. The patients complain also of pains in the limbs and back, and of much soreness, a bruised, fatigued, or tender feel, along the edges of the ribs, and in various parts of the body.

In its simple form and ordinary course, the disease abates of its violence after two, three, or four days, and the patient is usually convalescent before the termination of the week: but cough and much debility are apt to survive the other symptoms, and while these continue, the complaint is very easily renewed. Pre-existing disease, and peculiar constitutional habits and tendencies, modify considerably the character of the influenza, as it affects different persons. It is apt to be complicated with bronchitis, with pneumonia, with rheumatic affections of the joints, with neuralgic pains. I do not attempt to represent in detail its various phases; they are fit subjects of study for yourselves.

I have remarked that Cullen makes this species of catarrh to proceed from contagion. But the visitation is a great deal too sudden and too widely spread to be capable of explanation in that way. I will not say that the disease may not be in some degree infectious; for there is reason to believe that other epidemic disorders, having many points of analogy with the influenza, are somehow imparted from one individual to another, although they are mainly produced by some influence which resides in the atmosphere. There are facts in the history of influenza which furnish a strong presumption that the exciting cause of the disorder is material, not a mere quality of the atmosphere; and that it is at least *portable*. The instances are very numerous, too numerous to be attributed to mere chance, in which the complaint has first broken out in those particular houses of a town at which travellers have recently arrived from infected places. But this great and important question of contagion I hope to examine with you more rigorously on a future occasion. What I wish to point out now is the fact that the influenza pervades large tracts of country in a manner much too sudden and simultaneous to be consistent with the notion that its prevalence depends exclusively upon any contagious properties that it may possess. You are aware that it has recently seized upon all parts of this metropolis—and I believe I may say of nearly the whole kingdom—within the space of a very few days. It has been observed to occur also, at the same time, on land, and on board different ships which have had no communication with the shore, nor with each other. Thus it is stated in the *Transactions of the College of Physicians*, that on the 2d of May, 1782, Admiral Kempenfelt sailed from Spithead with a squadron, of which the *Goliath* was

one. The crew of that vessel were attacked with influenza on the 29th of May; and the rest were at different times affected, and so many of the men were rendered incapable of duty by this prevailing sickness, that the whole squadron was obliged to return into port about the second week in June, not having had communication with any shore, but having cruised solely between Brest and the Lizard. This happened in one part of the fleet. In the beginning of the same month, another large squadron sailed, all in perfect health, under Lord Howe's command, for the Dutch coast. Towards the end of the month, just at the time therefore when the Goliath became full of the disease, it appeared in the Rippon, the Princess Amelia, and other ships of the last-mentioned fleet, although there had been no intercourse with the land. Similar events were noticed in the epidemic of 1833. One or two curious instances of the sudden sickening of considerable bodies of men in different places at the same time, were related to me on good authority. On the 3d of April in that year — the very day on which I saw the first two cases that I did see of the influenza, all London being smitten with it on that and the following day — on that same day the Stag was coming up the channel, and arrived at two o'clock off Berry Head, on the Devonshire coast, all on board being at that time well. In half an hour afterwards, the breeze being easterly and blowing off the land, 40 men were down with the influenza, by six o'clock the number was increased to 60, and by two o'clock the next day to 160. On the self-same evening a regiment on duty at Portsmouth was in a perfectly healthy state, but by the next morning so many of the soldiers of that regiment were affected by the influenza, that the garrison duty could not be performed by it. I make no doubt that facts of a like nature have occurred during the present epidemic, and will be made known in due time. They illustrate several important points in respect to the disease: viz., the impossibility of accounting for its prevalence upon the principle of mere contagion — the suddenness of its invasion — and the early and extreme prostration of strength with which it is attended.

[In 1733 the influenza commenced simultaneously in London and in Flanders during the first week of January; at Paris, about the middle of the same month; and in Ireland, towards its termination; at Leghorn, about the middle of February; and at Naples and Madrid, near the end of the month. The same year it made its appearance in America, about the middle of October, first in the New England States; and was soon afterwards prevalent in the islands of Barbadoes and Jamaica. In a few months it is said to have extended to Mexico and as far South as Peru. In 1789, the disease made its appearance first in New York, in the month of September, and was prevalent during the same month in Philadelphia. Soon after, it spread over the whole of the Eastern and Southern States, and to the army, in the northwestern territory, under the command of General Wayne. About one month subsequently, it made its appearance at Grenada.

In its several visitations in this country it has usually commenced in one of the eastern States, and extended southwards along the seaboard, with more or less rapidity. In 1807, however, it showed itself first in New York, spreading thence, as from a centre, in every direction. It reached Canada, on the north, and extended to the Southern and Western States, in the course of three months. The amazing rapidity with which it diffused itself over the greater portion of the American continent, resembled more the fleetness of the wind than the natural course of a disease. Almost the entire population of a city, town, or neighbourhood, became in a few days subjected to its influence; and as it seldom incapacitated the majority of those affected by it from pursuing their ordinary occupations, there was heard in every street and place of resort, so much coughing, hawking, and wheezing, as to interrupt conversation; while in public assemblies the voice of the speaker, itself scarcely audible from the hoarseness produced by disease, was completely drowned by the coughing concert kept up by his auditory. In the subsequent occurrence of the influenza in our midst, nearly the same facts have been observed — very shortly after its first appearance in Philadelphia the greater part of the inhabitants of the city and surrounding country, became affected with it to a greater or less extent, and within a very short period it had attacked the inhabitants of nearly every portion of the United States. — C.]

The occurrence of epidemic catarrh, as well as of most other epidemics, is unques

tionably connected with some particular state or contamination of the atmosphere. What that state is, or what may be the kind of contamination, no one knows. The present epidemic followed hard upon the sudden thaw that succeeded the remarkable snow storm of the final week of the last year. A similar coincidence between the breaking out of the same disorder, and a sudden elevation of the temperature of the atmosphere, happened at St. Petersburg in the epidemic of 1782. "On a cold night (Maertens says), the thermometer rose 30° of Fahrenheit; the next morning 40,000 people were taken ill with the influenza." Now if every epidemic had been preceded by similar changes in the weather, we might resolve the universal prevalence and sudden accession of the complaint, into the effect of the cold and damp state of the air, produced by the thaw. But it is not so; for, as Dr. Hancock observes, there has not been any uniform connexion between any one sensible quality of the atmosphere as to heat or cold, rain or drought, wind or calm—and the invasion of the epidemic. "Et tempore frigidiori et calidiori, et flante tam Austro quam Borœa, et pluvioso et sereno cœlo, peragravit hæc omnes Europæ regiones, et omnia loca indiscriminatum." Irregularities and great vicissitudes of weather have however gone before the disease in very many instances: but sometimes one condition of the atmosphere, and sometimes another, has been its immediate forerunner: and the epidemic has frequently been observed to fall partially and capriciously; as a blight falls upon a field or district. Short, in his chronological history of the weather, says that thick ill-smelling fogs preceded, some days, the epidemic catarrh of 1557. Jussieu states that the grippe of the spring of 1733 appeared in France immediately after offensive fogs, "more dense than the darkness of Egypt." So also in 1775, Petit informs us that in France the disease was ushered in by thick noisome fogs. In the same year it visited the shire of Galloway in Scotland, where, we are told, "a continual dark fog and particularly smoky smell prevailed in the atmosphere for five weeks, the sun being seldom seen." Dr. Darwin has recorded that, in 1782, "the sun was for many weeks obscured by a dry fog, and appeared red as through a common mist:" and he supposes that "the material which thus rendered the air muddy probably caused the epidemic catarrh which prevailed in that year." You will call to mind here the dark fog which brooded over this city in the midst of the raging of the distemper about ten days ago, and which was repeated in a less degree, on Wednesday last (Feb. 1).

[Notwithstanding the influenza has occurred at all seasons of the year, whether hot, cold, damp, or otherwise; in every state of the barometer and hygrometer, still, if we cast our eyes over the various histories of its different visitations in Europe and America, it will be found that the weather immediately preceding, or during its occurrence was extremely unseasonable, or, at least, was marked by sudden alternations from cold to warm, or from dryness to moisture, or the reverse. Thus in 1675, we are informed by Sydenham, that the disease made its appearance in the end of October, at which period, the weather which had before been unusually warm, became suddenly cold and damp. In the winter of 1729, Dr. Gilchrist states, that at the time when the influenza occurred, the weather was thick, warm, and rainy. In 1762, according to Monro, the disease appeared in April, after a sudden change of weather from cold to extreme heat. In 1789, the weather preceding the visit of the influenza, is stated by Dr. Currie (*Diseases of the United States*) to have been calm, misty, and warm; and in the month of August, just as the disease made its appearance, we are told by Dr. Rush (*Med. Essays and Observations*) it changed suddenly to a degree of cold uncommon at that season of the year. In 1790, according to the last mentioned writer, the influenza appeared during an extremely variable winter—the weather suddenly changing from cold to warm, and the reverse. In 1807, we are informed by Dr. Currie (*Op. citat.*) that the Influenza made its appearance during a season marked by sudden changes of temperature, but throughout more wet and cold than usual. The period of its visit in 1816 was marked by very variable weather, and a mild and open winter. In 1826 it occurred towards the close of winter, during a thick, damp, and unusually mild state of the atmosphere; and the very severe epidemic of 1831 was preceded by great and sudden variations of atmospheric temperature followed by an unusually early winter.

Van Swieten, in his Commentary on the 1407 aphorism of Boerhaave, mentions the dependence of influenza upon a thick, vapory state of the atmosphere, and so far as

we have been able to obtain access to accurate accounts of the weather during those years and seasons when the influenza has prevailed, we have found it to be marked by variableness and moisture, or by sudden transitions from a degree of unusual heat to the opposite extreme.

It has been supposed that the occult morbid constitution of the atmosphere gives the predisposition to the disease, and impresses upon it its peculiar character of early and extreme depression, while the catarrhal symptoms are occasioned by the sensible properties of the atmosphere, especially by frequent and rapid changes in its temperature. However this may be, it is at least very certain that the latter increase the number of those attacked by influenza, and augment very materially its intensity. That during a season in which the influenza prevails, particular winds, and atmospheric vicissitudes are alone capable of producing the disease cannot, however, be doubted. In the account of the influenza, which prevailed in England in 1803, by Dr. Carrich, we learn that the inhabitants of that side of Richmond Terrace, on Clifton Hill, near Bath, which fronted the east, were universally attacked with the disease, while the south side, the great majority both of persons and families, in all other respects similarly circumstanced, escaped it entirely. Here the east wind was evidently the direct exciting cause of the influenza. — C.]

It has been observed also, that shortly before, or during, or soon after, the prevalence of these epidemic catarrhs — *epizootic* diseases have raged; various species of brutes, and of birds, have been extensively affected with sickness: while on some occasions prodigious swarms of insects have made their appearance. In short, a great variety of facts concur to render it probable that some peculiar condition of the air existed, which, though it might be favourable to the multiplication of some species of living creatures, such as the insects just referred to, operated as a poison upon the human body, and upon the bodies of many of the brute creation.

It is a very curious circumstance in the history of epidemic catarrh, and worthy of your reflection, that they *travel*; migrate as it were from one place to another; and moreover, that they hold, for the most part, to certain courses, in spite even of opposite winds, and of variations of temperature. It has been noticed that the influenza generally follows a westerly direction, or one from the south towards the north-west. In this remarkable property it resembles, as you may perhaps be aware, the epidemic cholera.

Although the general descent of the malady is, as I have said, very sudden and diffused, scattered cases of it, like the first droppings of a thunder shower, have usually been remembered as having preceded it. The disorder is most violent at the commencement of the visitation; then its severity abates; and the epidemic is mostly over in about six weeks. Yet the morbid influence would seem to have a longer duration. In a given place nearly all the inhabitants who are susceptible of the distemper suffer it within that period, or become proof against its power. But strangers who, after that period, arrive from uninfected places, have not, apparently, the same immunity.

The locality does not appear to be thoroughly cleared of the poison for some time: or perhaps a more cautious statement of the fact would be, that the disorder generally shows itself again in succeeding years, but in a milder and less general form. This must depend either upon some remaining dregs, or possibly some revival, of the injurious influence; or else upon some abiding predisposition impressed upon the bodies of men by its former visit. You may hear, every year, of Mr. *So-and-so* having the influenza. In many instances, no doubt, common sporadic catarrh is dignified by that name; but it is certain also, that many of the colds, and bronchial disorders, of the seasons which immediately follow a period of genuine influenza, are attended with much more languor, debility, muscular aching, and distress, than belong to an ordinary attack of catarrh.

All this is very curious and very mysterious. All this, or much of it, is true also of all the diseases which are known to prevail occasionally as epidemics. The facts that have now been mentioned respecting the influenza, warrant, I think, the conclusion that it does *not* depend upon any mutations in the ordinary and obvious qualities of the atmosphere: upon any degrees or variations, I mean, of its temperature, its motions, or its moisture; upon what is expressed in the single word *weather*. Con-

cerning a calamity so generally felt, and so obscure in its origin, conjecture, you may well believe, has not been idle. One hypothesis assigns the complaint to some change in the electrical condition of the air: to its becoming negatively electric: or to its being such as to cause an excessive accumulation of electricity in the animal economy. The facts adduced in support of these views are of this kind. Meat, sent up by means of a kite, high into the atmosphere, during the prevalence of the disease, has returned putrid. Large heavy separate clouds, in a state of negative electricity, have been observed just before the setting in of an epidemic. Thunder-storms, and tumults of the atmosphere, have occurred at the same periods. During the raging of one epidemic, 300 women engaged in coal-dredging at Newcastle, and wading all day in the sea, escaped the complaint. It has been thought that this exemption might be accounted for by supposing that the almost constant immersion of the body in a conducting medium prevented any undue collection of electricity.

Again, it has been conceived that the tolerably definite course of the epidemic, in its migrations, might be somehow connected with magnetic currents.

One of the most recent and most plausible conjectures respecting the exciting cause of influenza, is that which refers it to the presence in the atmosphere of an excessive quantity of *ozone*. The attention of physicians was first directed to this substance by M. Schönbein of Basle, in a paper which you will find in the *Medico-Chirurgical Transactions* for 1851. Pure or atmospheric oxygen, when exposed to the action of electrical sparks, is transformed into an odoriferous matter, which is therefore called ozone, and which is believed to be merely an allotropic form of oxygen. Most persons who have stood near an electrical battery at the time of its discharge must have been sometimes aware of the peculiar smell. The same odour pervades the air in thunder-storms. Now this ozone has remarkable purifying properties, which I need not stop to describe. It has also the effect, when breathed in large quantities, of irritating the mucous membrane of the air passages. While M. Schönbein was engaged in examining its chemical relations, he found that the inhalation of strongly ozonized air produced a painful affection of his chest—a sort of asthma, with a violent cough, which obliged him to discontinue for a time his investigations. Reflecting on this circumstance, he began to suspect that certain catarrhal disorders might be caused by atmospheric ozone. He got several physicians at Basle to compare their lists of catarrhal patients with his tables of atmosphero-ozonometric observations; and he and they were struck by the occurrence of an unusual number of catarrhal cases, on the days, or during the periods, when M. Schönbein's test papers showed that ozone was unusually abundant in the air.

This presumable explanation of epidemic catarrhs deserves, and doubtless will receive, a searching scrutiny, whenever the community may again be afflicted with influenza.

Another hypothesis, more fanciful perhaps, at first sight, than these, yet quite as easily accommodated to the known phenomena of the distemper, attributes it to the presence of innumerable minute substances, endowed with vegetable or with animal life, and developed in unusual abundance under specific states of the atmosphere, in which they float, and by which they are carried hither and thither. Myriads of these animalcules, or of these vegetable germs, coming in contact with the mucous membranes, and especially with that of the air-passages, irritate (it is imagined) those surfaces, and exercise a poisonous influence upon the system. Now the sporules of certain fungi, which ruin the health, and destroy the vitality of larger plants, on which they prey, are inconceivably small. I shall prove to you presently, that vegetable effluvia are capable of producing, in the human body, symptoms not very dissimilar from those of influenza. Again, that the waters of this globe swarm with living creatures, which are invisible by our unaided eyes, the microscope has taught us. Others, too minute to be estimated even by that wonder-showing instrument, in all probability exist. We cannot doubt that the gaseous fluid which surrounds this planet, equally teems with living atoms. We know that multitudes of insects, and of cryptogamous plants, infinite in number with respect to our finite powers of computation, are sometimes suddenly hatched or developed, in places which were previously free from them. It is easy to conceive that atmospheric infusoria (so to speak) may rapidly congregate, or vivify, in masses sufficient to render deleterious the very air we breathe. If this be so, we can understand how such a cause of disease may first

act here and there, and presently overspread large districts; how it may move, or be wafted from place to place, or be carried about by persons; how its course and operation may be circumscribed and definite; and how some germs or ova may remain after the visit, retaining their vitality, and ready in future seasons again to start into life and activity under favouring circumstances. Taking the insect hypothesis, and knowing, as we do, that some animal poisons, (that of small-pox, for example,) have the singular property of multiplying themselves in the human body, like yeast in beer, we may conceive that diseases, produced by animalcules, may thus infect the fluids of the body, and become contagious in the fullest sense of that term. Lastly, the uniform duration of these epidemics has been supposed to add probability to the notion that they result from the operation of some organic principle, which has its definite periods of growth and decay. All this is sheer hypothesis: but I have nothing better than hypotheses to offer you. You may choose from among them, or you may reject them all, as the bent of your minds may incline. That which most commends itself to my own acceptance, and which may also be most easily put to the test when the opportunity shall arise, is the *ozone* hypothesis.

The character of debility, which is so conspicuously impressed upon this disease, bears closely upon the treatment required for its cure, or its safe conduct. As in all other epidemics, the severity of the complaint is extremely variable in different persons. In some it proves a very trifling malady, which soon passes off, and requires little or no assistance from medicine. In others it is a very distressing affection, and lays the foundation for other and still more serious, though more chronic diseases: and in some, and more especially in the old and the unsound, it shows itself a very fatal disorder. The absolute mortality under the recent epidemic has been immense: the daily newspaper obituaries have been unusually long; and you may have remarked, that the ages of the persons whose deaths they announced were in almost all cases great. The funerals have been so frequent, that difficulty has been found in performing them without indecent hurry and confusion. One undertaker, of whom I was informed, had at one time 75 dead bodies to inter—*above ground*, as he expressed it; and mourning coaches, and black horses, could not be procured in sufficient numbers to meet the demand for them. The absolute mortality, therefore, I say, has been enormous; yet the relative mortality has been small. You will hear people comparing the ravages of the influenza with those of the cholera, and inferring that the latter is the less dangerous complaint of the two; but this is plainly a great misapprehension. Less dangerous to the community at large (in this country at least) it certainly has been; but infinitely more dangerous to the individuals attacked by it. More persons have died of the influenza in the present year than died of the cholera when it raged in 1832; but then a vastly greater number have been affected with the one disease than with the other. I suppose that nearly one-half of those who were seized with the cholera perished: while but a very small fraction indeed, not more probably than 2 per cent., of those who suffered influenza have sunk under it. The only fatal cases that I have seen have been in persons advanced in life, or in persons whose lungs were previously known to be unsound.

Now the *treatment* of the influenza is pretty well understood. The chief risk of mistake is that of being too busy with the lancet. Certainly those affected by this disorder do not well bear active depletion. Of course no one would think of blood-letting except the symptoms were severe, and the distress great; but even in such cases, much caution is requisite in adopting that remedy. If you find that the inflammation has extended to the pleura, or to the substance of the lungs, it may be necessary to open a vein, or to apply cupping-glasses over the chest: but this is a very unpleasant necessity. Such is the result of all that I have seen, and heard from others, of the present epidemic; and such is the result of the recorded experience of nearly all previous epidemics. You will find abundant evidence of this collected into a summary view by Dr. Hancock. In 1510, Dr. Short says bleeding and purging did harm. In 1557, bleeding was said to be so fatal, that in a small town near Madrid, two thousand persons died after it in the month of September. In 1580, Sennertus, after stating that where blood-letting was omitted, the mortality was not greater than one in one thousand, adds, "*Experientia enim hoc comprobavit, omnes fere mortuos esse, quibus vena aperiebatur.*" Dr. Ash observes that, in 1775, it was never necessary to bleed at Birmingham; and that, in a neighbouring town, three died who were

bled, and all recovered who were not bled. And a great deal more evidence to the same purpose you may find in the article I have referred to.

I believe the best plan of management—as far as any general plan can be laid down—is to keep the patient in bed, and after clearing the bowels by two or three grains of calomel, followed by a mild aperient, to give a couple of grains of James's powder every six hours, with a saline draught, and slops, till the first brunt of the disorder is over; and then, if the cough be troublesome and the breathing laborious, and much rhonchus, or sibilus, or crepitation be audible in the chest, to apply a blister, and to give expectorants and diuretics. What I prescribed a great many times was something of this kind: half a drachm of oxymel of squills, a drachm of the sweet spirit of nitre, and sometimes another drachm of pargoric, in almond emulsion. With respect to full doses of opium, when the feverishness is abated and the headache gone, I should recommend the same practice which I described in the last lecture. If there be any lividity of the skin, or of the mucous membranes, it is hazardous to give a full dose of opium. On the other hand, if there be no visible indication in the complexion that venous blood is circulating in the arteries, opium given at bed-time will have sometimes a magical effect in relieving distress, and (by giving rest and refreshing sleep) in recruiting the strength also. In cases in which the powers of the system are prostrate, and the face and lips are livid, and the patient is tugging to expectorate the mucus that is filling up his air-passages, you should have recourse to ammonia, to nourishing broths, and it may be to wine and water: and when all danger from the disease is over, but the patient remains feeble, languid, and out of spirits, then is the fit time to administer tonic medicines; and although snake-root and cascarilla are well spoken of by many practitioners, I know no tonics so good as the sulphate of quina, or of iron, for such patients.

As to external applications, mustard poultices, blisters, and the like—and to the inhalation of the steam of hot water,—these may each and all be very useful; but I have nothing to add concerning the time and manner of their employment to what I said upon the same subject in the last lecture.

There is one point in the treatment which I must not omit to notice, although I cannot tell you much about it from my own experience. Dr. Thomas Davies, an accurate observer, and one well qualified to form a judgment in the matter, states that he found a *mercurial* treatment answer well in severe cases, in the epidemic of 1833. He perceived that active depletion was not well borne, and discovering that in the bad cases there was always crepitation in the lower lobes of the lungs, he thought mercury was one of the most proper remedies to subdue the inflammation, and to occasion absorption of the fluid effused into the air-cells. He had severe cases to deal with. He says that it happened to be his duty to admit the patients into the London Hospital during the week the epidemic was at its height, and that thirty-two beds which were placed at his disposal were all soon filled with individuals labouring under the severe forms of influenza; so severe, that he believed the greater number of them would have perished if they had been allowed to wander about the streets, or even to have remained at their own homes, with the insufficient attention they could there have obtained. Only one or two of these patients were bled, but they were all put under the influence of mercury. This treatment commenced on Thursday, and all who, by Saturday night, were affected in the usual way by the remedy, safely and gradually recovered, with the exception of two; and one of these had hypertrophy of the heart, and diseased aortic valves. His object was not to salivate, but merely to make the gums tender. It was of course necessary that the action of the mercury should be prompt; and he found that the most quick and efficacious way of obtaining it was by rubbing in the linimentum hydrargyri.¹

There is a singular variety of catarrh produced by a peculiar local cause, and therefore requiring to be briefly noticed. I have now seen several unequivocal instances of it; and it has been observed and described by many writers. Dr. Bostock, in the *Medico-Chirurgical Transactions*, gives an account of this complaint as it was apt to attack himself. It is called the *catarrhus æstivus*, and by some the *hay-fever*, or the

¹ Influenza again prevailed in this country towards the end of 1847, and extended into the beginning of the next year. According to Dr. Farr it killed, directly or indirectly, not less than 5000 persons in six weeks.

hay-asthma. In Dr. Elliotson's lectures also, as published in the *Medical Gazette*, there is a good deal of curious information upon this malady, contained in letters addressed to him from practitioners in various parts of the country, in consequence of some previous remarks made upon it by him in a clinical lecture, which had also been printed. Dr. Elliotson speaks of it as a combination of catarrh and asthma. It consists in excessive irritation of the eyes, nose, and the whole of the air-passages; producing, in succession, itching of the eyes and nose, much sneezing occurring in paroxysms, with a copious defluxion from the nostrils; pricking sensations in the throat; cough, tightness of the chest, and difficulty of breathing, with or without considerable mucous expectoration. This complaint affects certain persons only, and in them it always takes place at the same period of the year, in the latter end of May, or in June, when the grass comes into blossom, or when the vernal hay-making is going on. It seems, in fact, to be produced by some kind of emanation from certain of the grasses that are in flower at that season, of the irritating qualities of which emanation some persons only, — and a very few persons in comparison with the entire community, — are susceptible. The disorder happens only at that one particular season; and it then attacks persons who are not remarkably subject to catarrh at other times, nor from the ordinary causes of catarrh; and if they avoid meadows and hay-fields, and the neighbourhood of hay-stacks, they escape the malady. Hence going to the sea-coast, — and especially to those parts of the coast that are barren of grass, — offers a means of protection: and when this cannot be done, such persons obtain refuge, in some measure, from the cause of the irritation, by remaining within doors, and shutting out as much as possible, the external air, during the hay-crop. One lady, who suffered annually from this strange affection, states that a paroxysm has been brought on by the approach of her children, who had been in a hay-field; and once this happened when the hay-harvest had been for some time over, upon their joining her at tea, after playing in a barn in which the hay of that year had been deposited. She was in the habit of flying to Harwich, or some other part of the coast, as the dangerous season came on. On one occasion, while walking on the shore at Harwich, she was suddenly attacked by the complaint, to her great surprise, as she was not aware of any grass being in the neighbourhood; but the next day she discovered that hay-making was in progress upon the top of the cliff at the time when she was walking under it. In another year, she being at Cromer, and an attack that she had suffered having quite subsided, and all the hay-making thereabouts being over, she was suddenly visited by the well-known symptoms, and on going into her bed-chamber perceived that they were building a large stack of hay in a yard near the house, having transferred it from a field five miles distant.

I was asked by Mr. Cheyne to see with him the wife of a stable-keeper near Regent Street. I found her suffering under what is popularly called "a crying cold:" pain in the situation of the frontal sinuses, streaming eyes, sneezing and defluxion from the nostrils, and very urgent dyspnoea, which was accompanied by loud wheezing. Symptoms of this kind had come on, suddenly, some days before: and her distress was then so great, that her husband proposed to drive her in a gig to consult a medical friend of his who lived at Islington. On their way thither, every symptom disappeared, and she felt at once quite well. She subsequently stayed a night or two, in comfort, with some relations in the city. Immediately upon her return home, the same symptoms recurred, with all their former severity, and resisted the means adopted for their relief by Mr. Cheyne, who had now been called in. He was soon led to suspect the cause of the attack, and of its obstinacy. There was a strong odour of hay in the house. The husband told him that his lofts were filled with a lot of hay which had recently arrived, and which had an unusually powerful smell. We learned that our patient was always worse at night, when the house was shut up; and better in the morning, when a free current of air blew through the open windows. We advised a temporary change of residence; but our advice was not followed until two days afterwards, the disorder meanwhile continuing, and increasing in intensity. Then the patient removed to lodgings not one hundred yards distant; and immediately all the catarrh and distress again ceased, and she passed a perfectly tranquil night. Afterwards she went into the country, and did not return till the odorous parcel of hay had been consumed, and a new stock laid in. She was

however revisited by some slight cough, and occasional dyspnœa — neither of which troubled her much or long.

Avoidance, then, of the ascertained source of the complaint is the best thing that can be recommended to these persons. You may read almost every year in the news papers that one of our English dukes has gone to Brighton to escape the hay-fever. But it is not in the power of every one to leave home for that purpose; and it has been found that the system is capable of being fortified in some degree against the pernicious effects of these vegetable effluvia. Mr. Gordon, of Welton, in Yorkshire, had communicated some interesting observations to the profession on this subject, before those of Dr. Elliotson were published. You may find Mr. Gordon's paper in the fourth volume of the *Medical Gazette*. He supposes that the aroma of the sweet-scented vernal grass, the *anthoxanthum odoratum*, is the principal exciting cause of the complaint. He found the symptoms more speedily and effectually removed by the tincture of lobelia inflata, than by anything else that he had tried at that time; and he recommended the cold shower bath as the best preservative against the attack. But in a subsequent communication to Dr. Elliotson, he states that the sulphates of quina and of iron, given in combination, had proved completely successful in emancipating from their tormenting disorder the two patients, from whose cases he had principally drawn up his account; although they had, in spite of all previous treatment, suffered an annual return of it for fifteen or twenty years.

The susceptibility of this troublesome affection of the respiratory mucous membrane, from a peculiar cause, which to most people occasions no uneasiness, appears sometimes to run in families; and this is nothing more than one might expect.

Dr. Elliotson, thinking it possible that the chlorides, which have the power of decomposing, and disarming of their noxious qualities, certain *animal* effluvia, might exert a similar control over the *vegetable* emanations that excite the hay-catarrh, suggested to one of the sufferers a trial of the chloride of lime, or of soda. He desired him to have it placed in saucers about his bed-chamber; to have rags dipped in it, and hung about the rooms of the house; to wash his hands and face with it night and morning; and to carry a small bottle of it with him, to smell from repeatedly in the course of the day: and this plan gave so much relief, — either by destroying the emanations, or by lessening the irritability of the mucous membranes, — that it was tried in other cases; and though it did not succeed in all, it did in most of them. Three patients out of four derived advantage from it. This expedient, therefore, is worth carrying in mind.

The son of an old acquaintance of mine was thought to have been benefited, in an attack of hay-fever, by the *Tinctura nucis vomicæ* of the Dublin pharmacopœia, taken in ten minim doses three times a day.

But the most hopeful preventive and remedy of this vexing disorder is that which has been lately suggested by Dr. Mackenzie. Led, as he has informed me, by the apparent analogy between certain irritable conditions of the skin, and of the mucous surfaces, and by the ascertained beneficial influence of *arsenic* upon some of the former, he tried that drug in the case of a gentleman suffering from hay-fever, in whom previous disappointments had produced despair of obtaining relief from any treatment. The use, however, of from three to five minims of the *liquor potassæ arsenitis*, in distilled water, immediately after each of his three daily meals, was attended with wonderful and speedy success. A like encouraging result followed the adoption of the same plan in other instances by Dr. Mackenzie, and by professional friends to whom he had mentioned it. Since the year 1850 I have recommended this remedy to several persons who complained of being annually harassed by the hay-fever: and from most of these I have subsequently received very favourable reports of its good effects. Dr. Mackenzie believes it to be most serviceable when the symptoms are of a catarrhal rather than of an asthmatic character.

There is another vegetable substance, better known to us, which produces, in some few individuals, symptoms very like those of the hay-asthma: I mean the powder of ipecacuan. I recollect a servant employed in the laboratory of St. Bartholomew's Hospital, when I was a pupil there, who had the peculiar ill-luck to be liable to this affection. Whenever that drug was under preparation, he was obliged to fly the place. This idiosyncrasy is not very uncommon. A very small quantity of the ipecacuan dust is sufficient, in such persons, to bring on a paroxysm of extreme

dyspnoea, wheezing, and cough, with singular anxiety, and great weakness. The distress usually terminates by a copious expectoration of mucus. There are persons who are similarly affected by the odour of cats.

These effects of a powdered root, and of certain emanations from grass or hay, lend weight to the hypothesis which ascribes the influenza to subtle vegetable matter floating in the atmosphere.

I would suggest a *trial* of the Respirator, as a defence against the particles of ipecacuan, and against the volatile exciting cause (whatever it may be) of hay-asthma.

Catarrh is very often met with in a chronic form; in other words, the mucous membrane of the air-passages is very liable to be affected with chronic inflammation. The accounts which you may read of this are exceedingly puzzling. Authors have endeavoured to draw nice distinctions between different *species* of chronic catarrh; sometimes according to varying qualities in the matters expectorated: thus you have *chronic mucous* catarrh — *pituitous* catarrh — *chronic pituitous* catarrh — and *dry* catarrh, which, after all, is *not* dry, but only accompanied by less expectoration than some of the others; and then again there is *symptomatic* catarrh. You will find all these enumerated by Laennec; and the majority of writers since his time have trodden with too submissive reverence in his footsteps. There are by no means such differences in the symptoms or in the proper treatment of the several varieties of chronic inflammation of the membrane in question, as to make these numerous subdivisions of any practical utility. Chronic or moderate catarrh is often a sequel of acute bronchitis; it is a very common accompaniment of disease of the heart; it frequently arises during the course of the febrile exanthemata; it is seldom entirely absent in cases of continued fever; and it is a form of complaint that is full of interest on this account, if on no other, that it has so often been mistaken, and is so liable to be mistaken still, for tubercular consumption; of which indeed it is very frequently the companion.

The *constant* symptoms of chronic catarrh, or bronchitis, are cough, some shortness of breath, expectoration of altered mucus. The *variable* symptoms those which are oftentimes of the most importance, as determining the slight or the serious character of the disorder, consist in the quantity and quality of the matters expectorated, and the presence or absence of wasting, and of hectic fever.

You will continually be meeting with cases of *this* kind. A person advanced in years has what he calls a slight cold, in the winter. He coughs, and expectorates a certain quantity of grey or transparent mucus. In the summer his cough diminishes, or ceases altogether. The next winter the same thing happens again; and each successive return of the colder seasons of the year brings back in increasing severity the cough and the expectoration: and if you listen to the breathing of such persons, while the cough is on them, you will find crepitation at the lower part of their lungs. Now these are examples, I believe, of a chronic state of slight inflammation of the membrane,—or it may be of passive congestion and effusion,—depending upon slowly advancing *cardiac* alterations. Peripneumonia notha is very apt to supervene on this condition.

But chronic bronchitis may take place at any age, as a sequel to the acute: just as active inflammation of other parts of the body is liable to degenerate into the chronic form; and such cases are sometimes very equivocal and deceptive. Several years ago, a lady became my patient, having cough, expectoration of puriform matter, night-sweats, and diarrhoea. She had had hooping-cough a short time before; but though the hooping and other symptoms proper to that disease had ceased, she continued to cough and to waste. Gradually she got thinner and weaker, her pulse became like a thread, and beat 120 times in a minute; she took to her bed, the diarrhoea was scarcely restrained by astringents and opiates, and I thought she could not live a week. And upon being pressed by her brother for my opinion, I said so. She had scarcely allowed me to listen to the sounds in the thorax: but I had once done so fairly, and I could find no morbid sounds, except at the lower part of the lungs. If I had trusted to that circumstance alone, I should have said that she had not pulmonary consumption; but I had not then so much faith in the indications afforded by auscultation, nor in my own accuracy of ear in such matters, as I might have now; and I concluded that she *was* dying of tubercular phthisis. Almost on the day,

however, on which I ventured to give this prognosis, some slight amendment began: and she did gradually recover, and is alive and quite well at this time. Now it is in cases of this kind that cures are performed by those who boast of curing consumption.

In truth, chronic bronchitis is, in some cases, as incapable of recovery, and as surely and progressively fatal, as tubercular phthisis itself, and even more so than some of the forms of phthisis. So long, however, as *no organic change* has taken place in the air-tubes, or in the mucous membrane lining them, these chronic forms of bronchitis that simulate phthisis in their general symptoms, are within the reach of cure. They are to be treated by counter-irritants to the chest—and by such measures as are calculated to relieve the most urgent symptoms. Opiates for cough, or for diarrhœa. Sometimes the patients bear steel well, and then it is almost sure to have a beneficial effect. Sometimes sarsaparilla appears to do good; but, as far as I have observed, one of the most effectual restoratives in these cases is to be found, when the weather and the strength permit, in frequent change of air and place; in gentle gestation in a carriage, or in a boat; and in a nourishing but bland and unstimulating diet. When the membrane, and the tubes which it lines, become *altered in structure*, and pour forth a fluid which has all the qualities of pus, hectic fever generally is present, and the chronic disease tends, slowly perhaps, but surely, to death.

There are certain cases of chronic bronchitis which are especially remarkable, on account of the great abundance of the bronchial secretion: so great that the patients appear to die principally from the daily exhausting drain thus made upon the system. There are sometimes no other evident signs of inflammation; so that, as Andral observes, one might be led to separate these fluxes from the truly inflammatory affections. They differ from them apparently in their nature, and certainly in the treatment which they require. Andral has detailed two or three instances of this kind in his *Clinique Médicale*. The patients expectorated every day large quantities—a pint or more—of frothy fluid, resembling weak gum-water in colour and consistence. They had no fever; neither frequency of pulse nor heat of skin; but they were exceedingly pale, like persons blanched by hæmorrhage, and their emaciation and weakness were also extreme. Very little appreciable deviation from the healthy state was detectable when the lungs and heart were examined after death.

It does occasionally happen that even larger quantities—three or four pints daily—are, for a considerable period spat up, without much wasting.

Andral asks, whether, in such cases as these, which certainly occur, although they are not very common, the first indication of treatment should not be to check and diminish the excessive bronchial secretion; to treat it as you might treat a gleet of the other mucous membranes, with balsams, administered either by the stomach, or in the shape of vapour. He conjectures that it might have been in cases of this nature that the vapour of tar, and tar-water, were once thought to be so useful. Probably the creasote would be well adapted to such cases. Certainly I have seen the excessive expectoration diminish, and the patients gain strength, under the use of the balsams; the compound tincture of benzoin, for example; a form of medicine much employed, formerly, and too much neglected, I apprehend, at present.

[Balsam Copaiba will be found a very valuable remedy in this form of bronchitis. Dr. La Roche relates in the *North American Medical Journal*, Vol. III., several cases illustrative of its efficacy. — C.]

Another remedy from which I have derived great advantage in some cases of the same kind, is the sulphate of iron, given in two or three-grain doses, in the compound infusion of roses, thrice daily. When there is any fever present, these remedies are apt to augment it: but when the pulse is quiet, and the skin cool, I am quite sure that they are often of the greatest service; and this you will likewise find to be the opinion of various practical authors.

There is another very remarkable condition of the pulmonary mucous membrane, constituting also, I imagine, a species of chronic inflammation, and characterized chiefly, like the last, by the matters expectorated. I mean that state in which a firm substance, resembling a false membrane, forms in the smaller bronchi and in their ramifications, and is coughed up, from time to time, in fragments. I mentioned in a former lecture that the false membrane of croup sometimes descends a long way into

the bronchi; even to their extremities. But I am speaking now of a different and less acute form of disease, in which the trachea being unaffected, concrete masses, evidently moulded in parts of the hollow bronchial tree, are spat up; somewhat like bunches of worms, or the branching roots of a small plant. This I presume to be uncommon; for I have met with it twice only in my life. It has been described, however, by several observers. The first, Dr. Warren, has a paper upon it in the first volume of the *Medical Transactions*, where he gives representations of the substances coughed up, which he calls *bronchial polypi*. Dr. Paris has told me that a patient of his coughed up considerable quantities of these branching casts of the ultimate air-tubes, now and then, for a long period. An interesting paper of Mr. North's, on the same subject, was read at one of the evening meetings at the College of Physicians. That gentleman possesses some beautiful specimens of these misnamed polypi. Sir R. Carswell gives a figure representing them. When the affection is extensive, it is attended with great distress, and dyspnoea, and violent fits of coughing; and the symptoms are wonderfully calmed upon each expulsion of the solid matter. The surprise is that such patients should ever recover; but I have never heard of an instance in which the complaint proved fatal.

The two examples of it which have fallen under my own observation, were invested, by the circumstances attending them, with a peculiar interest. They occurred, within less than a twelvemonth of each other, in the persons of two brothers, of middle age, the one a barrister, the other well known to you all as one of my most valued colleagues in this place. Both of them were, and are, remarkably stout, strong, and healthy men.¹ In both cases the expulsion of the so-called polypi was preceded by hæmoptysis, which came in considerable gushes, and was repeated at intervals of a few days, until the solid matters began also to be expelled, and then the hæmorrhage soon subsided.

The barrister, after having been annoyed for nearly a year by some huskiness of the voice, spat up, all of a sudden, a small quantity of bright blood; and soon afterwards expectorated several ramifying masses of tolerably firm consistence, resembling fibrinous coagula of blood, deprived of most of its colouring matter. Some of them, which I saw and examined, were solid; others, I understood, were hollow. I found slight circumscribed crepitation in the lower and posterior part of his left lung. This trivial degree of hæmoptysis, with the expulsion of what looked like casts of the interior of a bronchial tube, was once or twice repeated within a few days. He had no fever—no dyspnoea. Mercury, *inter alia*, was prescribed; but as the patient did not feel in any way ill, I believe he soon became tired of physic, and of medical restraint. Whenever I have since seen him, he has appeared to be in perfect health.

Of the Professor's illness I saw more. In the midst of health which had been uninterrupted, save by a solitary fit of gout some years before, he also spat some mouthfuls of florid blood. He had no cough, but the hæmoptysis was accompanied by a rattling sensation in the right side of his chest.

For about three weeks he continued, at intervals varying from three to six days, to expectorate blood, in gushes. The smallest quantity brought up on any one occasion was two ounces; the largest, eight. Just above the right nipple the respiratory murmur was mingled with large crepitation, which was always sensibly increased, and quite perceptible by the patient himself, during the attacks of hæmorrhage. In the intervals between them his breathing and his pulse were perfectly tranquil and regular.

With the florid blood came up, in general, some black coagula; and at the end of three weeks, or thereabouts, in these black masses ragged shreds of a different and firmer material began to be visible: and presently afterwards, complete branch-like casts of the ramifying air-tubes were expelled; and the bleeding ceased.

Of these casts there were two kinds: the one solid, somewhat coloured, evidently fibrinous, and resembling the branching coagula that may sometimes be drawn out of the arteries in the dead body; the other white, membranous, tubular, but ramifying also. None of them were of very firm consistence.

Till these substances made their appearance, our anxiety about the patient was extreme, and he underwent some rigorous discipline at our hands. He was confined

¹ Since this was written, Professor Daniell has been suddenly cut off, to the great grief of all who knew him, by a stroke of apoplexy.

to bed, forbidden to speak, kept strictly to the slenderest slop diet, several times bled, and extensively blistered. Lumps of ice were given him to swallow, and pounded ice was applied to his chest whenever the blood broke forth afresh. He took mercury till his gums were tender, and afterwards the acetate of lead, and other reputed styptics.

To most of this I was a consenting party; but looking back upon the ease now that its nature and result are known, I must confess that the treatment, though fairly justifiable at the time, was unnecessarily active.

Mr. North, in the paper to which I have alluded (you may see it in the twenty-second volume of the *Medical Gazette*), draws a distinction, of which he gives the credit to Dr. Cheyne, between the hollow, membranous conerctions, expelled without any blood; and the solid branching masses which accompany or succeed hæmoptysis, and are obviously mere coagula of blood moulded in the smaller air-tubes, where it had stagnated. He points out the comparatively harmless character of the cases in which the first occur; and the far more serious import of the second: the hæmorrhage denoting the presence of some organic mischief within the thorax, and the "polypous conerctions" being simply an accident of the hæmorrhage.

I doubt the accuracy of this distinction. The brothers of whom I have spoken continue to be, as they were before, free from any symptom or suspicion, either of cardiac or of pulmonary disease. Moreover, in hæmoptysis depending upon tubercles in the lungs, or upon organic disease of the heart, these conerctions are very rarely observed. I have never seen them in such cases, common as such cases are. The barrister had a husky voice, and the Professor was noticed to have been often "clearing his throat" for some time before the first eruption of blood: from which circumstances I infer a previous unhealthy state of the mucous membrane. Upon the whole I incline to the views expressed by Dr. Todd, with whom I had the advantage of consulting in the latter case — that a chronic and limited inflammation of certain of the bronchial tubes first occurred, disclosing itself by no marked symptoms, but leading to the formation of tubular membranes; that, after a while, these membranes began to be detached; that hæmorrhage resulted, and continued till the separation was complete; and that, at the same time, some of the extravasated blood coagulated in, and took the shape of, the air-tubes, and was afterwards expectorated.

I understand that the barrister has since had a recurrence of this strange complaint, which he treated very lightly, and soon got rid of.

He entertains a fixed belief that his attacks were attributable to the presence of one of Dr. Arnott's stoves in his chambers; the heated atmosphere of which always produced a slight feeling of constriction and distress within his chest. Whether this notion be well or ill founded I cannot pretend to say: but it is curious that the Professor also had been using a similar stove, which, placed in his sitting-room, warmed both it and his bed-room adjoining it.

In the fifth volume of the *Transactions of the Pathological Society of London* is contained an interesting summary by Dr. Peacock, of thirty-four cases, recorded by various authors, in which fibrinous casts were expelled from the air-tubes.

From this summary it would appear:—

That the affection occurs more frequently in males than in females.

That though it is not limited to any period of life, it is most common in persons of middle age.

That generally the moulds proceed from bronchial tubes of the third or fourth magnitude, and from their branches; the trunks having the average size of an ordinary goose-quill.

That hæmoptysis is quite as often absent as present; and that the only pathognomonic sign of the complaint is the expectoration of the membranous shreds or casts.

That the attacks generally cease after a week or fortnight, but are sometimes protracted over several weeks; and that they are apt to recur, from time to time, for months or years.

That in itself the complaint is not a dangerous one; and that when death takes place during its progress, the fatal issue results from some disease of which the membranous exudation is merely a complication. Some of the patients who died were manifestly consumptive; and most of those in whom this peculiar expectoration has

been noticed were originally of delicate constitution; or had shown previous tokens of pulmonary weakness, or of pulmonary disease.

A word or two more, before we separate, as to the morbid anatomy of these tissues.

Chronic inflammation of the aërial mucous membrane may lead to changes in its colour; or to thickening of the membrane; or to ulceration; or to dilatation of the bronchi, and of their ramifications. And it is proper that you should be informed respecting these morbid conditions.

In general, when chronic inflammation has existed during life, the mucous membrane is found to be red: but it is not a bright redness; it is rather a livid, or violet, or brownish tint. And what is very curious, in some instances in which all the symptoms of inveterate bronchitis, with *puriform* expectoration, had been present, the inner membrane of the air-passages has been found scarcely rosy — or even perfectly white — throughout its whole extent. Of course we are not to infer from this that there has not been *inflammation*; for the same thing is known to occur in the intestinal mucous membrane, in that of the bladder, and even in serous membranes. Where pus is poured forth there must have been inflammation.

One effect of inflammation, as I formerly showed you, is a softening of the membrane; but this is a much less common result of inflammation in the mucous membrane of the bronchi, than in that of the digestive organs. In regard to ulceration likewise there is a great difference between the two mucous surfaces: in that of the air-passages it is comparatively rare.

Thickening of the mucous tissue occurs also in various degrees: and in connexion with the various morbid conditions of this membrane, I must bring briefly under your

FIG. 44.

Dilated bronchi, from a female aged 52, who had suffered from chronic pneumonia and bronchitis for three years; the pulmonary tissue intervening between the bronchi was much condensed.

FIG. 45.

Uniform dilatation of the bronchi.

notice some remarkable changes, produced by disease, in the tubes which it lines; and especially the dilatation of those tubes.

There are two or three varieties of this dilatation. In the first of them, one or more of the bronchi present, throughout the whole or the greater part of their extent,

an increase of capacity which is very often considerable: so that tubes which result from the fourth, or the fifth, or even the sixth division of the principal bronchus of each lung, may equal or exceed in diameter that bronchus itself. Tubes that ought to be no bigger than a crow-quill may become as large as the finger of one's glove. The parietes of the dilated tube are thickened, and its circular fibres hypertrophied, as you may see in this preparation, and in Sir R. Carswell's plate. Sometimes this kind of dilatation is seen in a single branch only, sometimes in many branches. It may affect the bronchial ramifications of an entire lobe. It is more common in the branches of a bronchus than in the bronchus itself.

With respect to this sort of dilatation, it is observable that the pulmonary tissue lying in immediate contact with the enlarged tubes is usually, if not always, impermeable by air; it may be from some bygone inflammatory process; it may be from mere collapse and its attendant atrophy. Dr. Corrigan, and after him Dr. William Gairdner, have shown the strong probability that the dilatation is a consequence of this unnatural condition of the surrounding tissue; and that it is gradually produced by "the expansive forces of inspiration acting upon the bronchi of atrophied lung."

In the second variety of this change, instead of the uniform dilatation of one or more bronchial tubes, throughout their whole extent, we find a belying, or globular expansion, at the extremity of one of them; and the walls of the tube, instead of being thick and hypertrophied, are wasted, and in a state of atrophy. The tissues composing the tube are often so thin, that when the cavity, for such it must be called, is laid open, the colour and structure of the pulmonary tissue may be seen through them. These cavities are generally found filled with a thick, tenacious, straw-coloured, muco-purulent fluid. They are seldom met with except after those affections which

are characterized by considerable secretion from the membrane, and by much and repeated cough: as after some forms of chronic bronchitis, and after whooping-cough.

A third variety of dilatation is that in which the same bronchus bellies out in different places; is dilated at intervals; so as to present in its course a series of successive enlargements and contractions. Here, again, the walls of the bronchi, though they may be traced in the parts dilated, do not appear to be thickened, but rather are diminished in thickness. This variety of dilatation is more frequent in children than in adults.

Dr. William Gairdner gives a plausible account of the formation of these globular or sacculated expansions. He states that, after bronchitis, pus is sometimes found imprisoned in the central air-branches of a collapsed lobule. The coats of these tubes, injured and softened by disease, gradually give way and ulcerate; and the pus, which accumulates, is at length surrounded by a false membrane exactly similar to that of an abscess in any other part. The continuity of this membrane with that of the ministering bronchus may either exist from its first formation, or be established subse-

Obliteration of the bronchi.

quently. These "bronchial abscesses" communicating at length freely with the tubes leading to them, may afterwards be expanded beyond their former dimensions by the inspiratory force.

In whatever way dilations of the bronchi may take place, it is to be expected, when they are numerous or extensive, that they should be attended with some habitual shortness of breath.

But the most important consideration arising out of these conditions of the bronchi, is this; that the signs, both general and physical, by which they are accompanied, are apt to be exactly those which are most distinctive of phthisis. And it is on that account that I have now described these changes. I shall revert to them again when I come to the symptoms, revealed by auscultation, of tubercular disease of the lungs.

LECTURE L.

Hooping-cough: symptoms; duration; complications; pathology; treatment.—Pneumonia: its stages and morbid anatomy; auscultatory signs.

I HAVE yet to consider one very important disorder, which is usually classed among the catarrhal affections, but which is marked by features so peculiarly its own, as to distinguish it effectually from every other form of disease. I allude to *hooping-cough*: a remarkable complaint, well known everywhere, I believe, and much dreaded by parents. It has received a variety of names: chin-cough; kink-hoast; coqueluche; tussis convulsiva; tussis ferina; and *pertussis*. This last name, which Sydenham bestowed upon it, and which was adopted by Cullen, is the technical appellation of the disease in this country, as hooping-cough is the popular.

The phenomena that characterize hooping-cough are, I say, remarkable. It begins with the symptoms of an ordinary catarrh arising from cold. The child (for it is most especially a disease of children) has coryza, and coughs: and mothers and nurses are aware that the disease commences in this way, and express their apprehensions lest it may *turn* to the hooping-cough. After *this* the *catarrhal* stage, has lasted eight or ten days, or a fortnight, or sometimes a day or two longer, that kind of cough begins to be heard which is so distinctive. It comes on in paroxysms, in which a number of the *expiratory* motions belonging to the act of coughing are made in rapid succession, and with much violence, without any intervening inspirations; till the little patient turns black in the face, and seems on the point of being suffocated. Then one long-drawn act of *inspiration* takes place, attended with that peculiar crowing or hooping noise, which denotes that the rima glottidis is partially closed, and which gives the disease its name. As soon as this protracted inspiration has been completed, the series of short expiratory coughs, repeated one immediately after the other till nearly all the air appears to be expelled from the lungs, is renewed; and then a second sonorous back-draught occurs: and this alternation of a number of expiratory coughs, with one shrill inspiration, goes on, until a quantity of glairy mucus is forced up from the lungs, or until the child vomits, or until expectoration and vomiting both take place at once. During the urgency of the paroxysms the face becomes swelled, and red or livid, the eyes start, the little sufferer stamps sometimes with impatience, and generally clings to the person who is nursing him for support, or lays hold of a chair or table, or of whatever object may be near him, to diminish (as it would seem) the shock and jar by which his whole frame is shaken. As soon as expectoration or vomiting have happened, the paroxysm is over. The child may pant a little while, and appear fatigued; but commonly the relief is so complete, that he returns immediately to the amusements, or the occupation, which the fit of coughing had interrupted, and is as gay and lively as if nothing had been the matter with him. When the fit terminates by vomiting, the patient is in general seized immediately after with a craving for food, asks for something to eat, and takes it with some greediness.

Each paroxysm may consist of several alternations of the gasping coughs, and the characteristic hoop or kink; but Cullen remarks, that the expectoration or the vomiting usually takes place after the second coughing, and puts an end to the fit.

The number of paroxysms that occur in the twenty-four hours is variable also: and they come on at irregular intervals. The nocturnal paroxysms are commonly more

severe than those of the day. When the complaint is uncomplicated, the child, during the intermissions, appears to be quite well. This is another striking feature of the disorder. In the earlier paroxysms the mucus expelled is scanty and thin; and in proportion as this is the case, the fits are the longer and the more violent. By degrees the expectoration becomes more abundant: and sometimes it is very copious: at the same time it is thicker, and more easily brought up; and on that account the fits of coughing are less protracted.

The ordinary duration of the disease is from six weeks to three months; but it may run its course, I believe, in three weeks; and it may continue for six months, or more.

In an uncomplicated case, if you listen at the chest during the intermissions, you will probably hear the sounds that are proper to catarrh—some degree of rhonchus or sibilus: and in some parts there may be puerile respiration; and if you percuss the thorax, you get the natural hollow sounds. But what happens when you apply your ear to the chest during the paroxysms of coughing? Why, the information given us in this case by auscultation is very curious. You may perhaps hear, between the short explosive shocks of the cough, some snatches of wheezing, or of vesicular breathing; but during the long-drawn noisy inspiration that succeeds, all *within* the chest is silent. This is supposed to result from the slow and niggardly manner in which the air passes towards the lungs through the chink of the glottis, which is spasmodically narrowed. It may also depend, in part, as Laennec supposed, upon a spasmodic condition of the muscular or contractile fibres of the bronchi and their branches. When the fit is at an end, the ordinary sounds of healthy, or of catarrhal respiration are resumed.

Children are very susceptible of this complaint; and it is a complaint which spreads by *contagion*. Hence it follows that few children escape an attack of it. It is also one of those contagious maladies which do not in general affect the same individual twice; and hence again it follows that it is rarely met with in adults. Such is the fact; and such, I apprehend, is the explanation of it. It is not that adults are insusceptible of hooping-cough: for adults that have not had it during their childhood are readily affected when exposed to the contagion. But it is that the disorder, with very few exceptions, protects the system somehow from its future recurrence; and that most adults have *had* it when they were young, and for that reason do not take it afterwards.

During the very early periods of infancy, *i. e.*, within the first two or three months, hooping-cough is said to be rare: I mentioned a case, however, before—and I have read of others—in which the disorder appeared to have been contracted before the patient was born. My bedmaker's daughter in Cambridge had a child ill with hooping-cough in the house with her during the last week of another pregnancy, and the new comer hooped the first day he came into the world.

As long as this disease is uncomplicated—unmixed with inflammation, and therefore, unattended with fever, or only with that slight inflammatory condition proper to mild catarrh—it is seldom a *dangerous* disease. Probably it *will*, under the most favourable circumstances, run a certain course. By degrees the violence and the frequency of the paroxysms diminish; they occur only in the morning and the evening, then in the evening alone, and at length they cease altogether. But for some time after the disorder has apparently come to an end, if the child take cold, and get a cough, the cough is apt to assume a spasmodic character, and to be attended with a hooping noise in inspiration.

Nevertheless, when it is very intense, the disorder *may* have a fatal issue, without any organic complication. Before the little patient has fairly rallied from one paroxysm, another succeeds it; the spasmodic closure of the larynx is more and more complete and lasting, until, at length, little or no air can pass; the characteristic hoop becomes short and faint, or ceases altogether; and the child dies of apnœa.

Unfortunately, too, hooping-cough is, in a great many cases, not simple—not uncomplicated. It becomes mixed up with other kinds of disease, in the chest, or in the head. In the chest severe bronchitis supervenes upon it, or inflammation of the substance of the lungs; and then fever is lighted up, and permanent dyspnœa is present. When the disorder has been long drawn out, and has at last terminated fatally, dilatation of the bronchi, such as I described in the last lecture, is often found

upon dissection; still more commonly what is called *emphysema* of the lungs — a change which I have yet to bring before you; but most frequently of all, pulmonary collapse of the lobular kind.

Collapse of the lung I have already shown you to be ordinarily the result of obstruction of the air-tubes by mucus accumulated within them. The risk of such obstruction is always present in whooping-cough. But there are co-operating causes; to most of which these young patients are also liable. Whatever impedes the free and full indraught of air may be a co-operating cause: the spasm therefore which, narrowing the inlet, diminishes the supply of air; a tumid abdomen, hindering the contractions of the diaphragm; weakness of the muscles of inspiration, arising from general debility. And there is yet another accessory cause, which is peculiar to the early years of life. In the full inspiration of an adult the thorax is enlarged by the separation and the upward movement of the unbending ribs, and by the simultaneous descent of the diaphragm. But in young children, when the inspiratory act is difficult and forced, the ribs yield under the power of the contracting diaphragm, which drags them inward, and thus the full expansion of the lung is stinted. In this way permanent deformity of the chest is sometimes produced. We need not wonder then that more or less of pulmonary collapse should be a nearly constant phenomenon after death from whooping-cough.

Neither can we be surprised that the disease frequently leads to cerebral disorder. During the fits there is a great and visible determination of blood towards the head, or rather a detention of the blood in the veins that proceed from the head; — passive mechanical congestion: the transmission of the blood through the lungs being obstructed, and its return from the head interrupted. Hence, the face becomes turgid, the eyes are prominent, the superficial veins full and projecting, the lips and cheeks turn livid; sometimes hæmorrhage takes place from the nose or ears; or the eyes become blood-shot; or the patient actually falls into convulsions; nay, apoplexy is occasionally the result of the straining; and when life is not thus suddenly cut short, chronic mischief is apt to be set up in the brain, and the child may ultimately die hydrocephalic.

All this is the more to be feared in proportion as the child is the younger. Head affections are particularly to be dreaded in scrofulous children; and in any children during the first dentition. When the disease occurs within the first two years of life, it is usually attended with convulsions: and many more die within that period than afterwards. And Cullen's remark is undoubtedly true; that the older children are, the more secure they are, *cæteris paribus*, against an unhappy event.

Whooping-cough may be complicated also with a disordered condition of the bowels; and with infantile remittent fever. This complication is more accidental, and less a consequence of the whooping-cough than the former; but it may very materially add to its peril.

Dr. Cullen was of opinion that the complaint may exist in even a milder form than that which I have called simple whooping-cough. He thought he had seen "instances of a disease, which, though evidently arising from the chin-cough contagion, never put on any other form than that of a common catarrh." Others again believe that adults may have it without whooping. But all this seems to me very doubtful. Catarrh is an exceedingly common malady; and I should be slow to consider any case a genuine case of pertussis, unless the characteristic paroxysms of coughing, and the stridulous inspiration, were present.

Divers opinions have been held respecting the seat, and respecting the nature, of whooping-cough. Some suppose it to have its seat in the brain: others that it is a specific variety of catarrh, and has always therefore more or less of an inflammatory character: others again, looking to its spasmodic symptoms, ascribe the disease to some morbid influence exercised upon the pneumogastric nerve: and this last I believe to be the truest view of the matter. The disorder belongs to a very remarkable group of blood-diseases, of which I shall have much to say hereafter, and is produced by an animal poison. Certainly the simple form of the disease is often unattended with any appreciable fever: and that is a strong ground for concluding that its peculiar phenomena are not necessarily connected with inflammation. They who have ascribed the complaint to a morbid condition of the brain have deduced that opinion, I presume, from the cerebral symptoms that are sometimes so plainly marked

in whooping-cough. But these symptoms are oftener, to all appearance, the consequence, than the cause, of the paroxysms of coughing. I would suggest it as an interesting point for your future inquiry, whether the pathology of whooping-cough may not receive some elucidation from the researches of the late Dr. Ley respecting the crowing inspiration of infants. You remember his suggestion, that mere inflammation of the mucous membrane of the air-passages might cause swelling of the absorbent glands of the bronchi, or of the neck. This is a circumstance which I have myself long thought probable, from having found enlargement of the cervical glands springing up during the existence of pulmonary irritation. Take notice that the spasmodic fits of whooping-cough are always preceded for some days by mere catarrhal symptoms. Observe further how the parts supplied by the pneumogastric nerve are affected in these paroxysms: the larynx, the lungs, the stomach. This conjecture, that the crowing inspiration of infants, and the crowing inspiration of whooping-cough—though quite distinct affections—may both depend upon irritation of the recurrent nerve, or of the pneumogastric nerve generally; and that even the irritation might in both cases arise out of enlargement of the glands that lie in the course of that nerve: this natural conjecture had presented itself to Dr. Ley's mind; for, towards the end of his book, I find this note:—"Recently four children have been brought to my house, labouring under whooping-cough. In all, the glandulæ concatenatæ near the trachea were very considerably enlarged. Is this (he says) merely an accidental combination? or is there any essential connexion between the two? May it not be that an enlargement of these glands, from a specific animal poison, similar to that of the parotid glands in mumps, is, after all, the essence of whooping-cough?" The subject at least deserves inquiry and further observation."

In corroboration of this conjectural view of what *may* ultimately prove to be the true pathology of whooping-cough, I may remark that among the morbid appearances described as being met with after death from that disease, "an unusual swelling of the bronchial glands" is set down. It is also stated, by some of the Germans, that that portion of the pneumogastric nerve which lies in the cavity of the chest has been sometimes found red. Yet I should lay no stress upon this; for others have asserted that they have looked in vain for this redness: and even supposing it to exist, it is no sure or safe token that there had been inflammation of the nerve. The nerve, all things considered, would be likely to become tinged of that colour soon before, or even after, death, from the gorged condition of the lungs. In some cases, as you may well believe, serous fluid is met with in the ventricles of the brain, or in the meshes of the pia mater: in others the consequences of inflammation are traceable in the bronchi, the lungs, or the pleuræ. Portions of what is called hepatized lung are not unfrequently seen in the fatal cases: though less frequently than portions of collapsed lung.

[The leading opinions in relation to the pathology of whooping-cough, may be referred to one or other of the following heads.]

1st. With some the disease is essentially a *spasmodic affection of the air-passages*, arising from a primary irritation, inflammatory or nervous, of the brain, or of one or other set of the respiratory nerves. This theory, variously modified, is that advocated by Hoffmann, Cullen, Hufeland, Jahn, Löbel, Holzhausen, Leroy, Coiter, Guibert, Breschet, Gardien, Bauer, Albers, Clarus, Webster and Copland. Dr. Webster considers the affection of the respiratory organs to be secondary, and dependent on a primary inflammatory irritation of the brain or of its membranes, or of both. Most of the advocates of the nervous theory regard the pneumogastric nerves as the primary seat of the affection; others, however, locate the irritation in the phrenic nerves—the principal of these are Jäger, Lobenstein, Löbel and Leroy; others again, as Albers of Bremen, Pinel, Laennec, Blache and Roe, refer the irritation to both the mucous membrane of the bronchi and the pneumogastric nerves.

2d. Others consider the disease as an *inflammatory affection* of some part of the *mucous membrane of the air-passages*; this opinion numbers among its advocates, Darwin, Watt, Marcus, Alcock, Dewees, Dawson, Pearson, Guersent, Fourcade-Prunet, Boisseau, Broussais, Rostan and Dugés. Dr. Watt believed it to be "in all cases, an inflammatory disease, whose chief seat is in the mucous membrane of the larynx, trachea, bronchi, and air-cells, possibly attended with a minute exanthematous crup-

tion there." He considers that, when mild, "this inflammation runs its course without materially disturbing the other functions of the body, or even the functions of that very membrane in which it is seated, and that whenever whooping-cough proves dangerous or fatal, it becomes so by the degree of inflammation in the natural seat of the disease, or by that inflammation extending or being translated to other parts." Most advocates, however, of the inflammatory origin of the disease, limit the inflammation to the trachea and bronchi. Dawson confines it, at first, to the larynx, or, strictly speaking, to the glottis—an opinion, by the way, not widely differing from that of Astruc, who of old describes the disease as an "inflammation of the superior part of the larynx and pharynx."

3d. Many view the complaint as at first inflammatory, and afterwards spasmodic, or as a specific inflammation of the respiratory mucous membrane combined with irritation of the respiratory nerves, in consequence of which the muscles to which the latter are distributed are thrown into spasmodic action; the nervous irritation continuing after the inflammation has ceased. This doctrine, variously modified, is a favourite one with the writers on whooping-cough. Desruelles makes the disease to consist in a primary inflammation of the bronchi, complicated with a consecutive cerebral irritation, which by its influence over the diaphragm and other respiratory muscles, and over those of the larynx and glottis, changes the simple cough of bronchitis into one of a convulsive character. This opinion is the one adopted, also, by Dr. C. Johnson in his able article on whooping-cough in the *Cyclopædia of Practical Medicine* (*Philadelphia Edition*,¹ vol. 2, page 453): other writers who admit the *occasional* presence of cerebral disease, consider this to be invariably secondary to the bronchial affection: of this opinion are Boisseau, Begin, Otto and Vondembush.

4th. By not a few, especially of the older medical writers, whooping-cough is referred to an irritation of the stomach and lungs. Rosen, who supposed the disease to be produced by either an insect or a morbid poison, partly inhaled into the lungs and partly swallowed with the patient's saliva, considered that the stomach suffered more from the irritation than the lungs. Danz believed that the irritation is seated primarily in the stomach and bowels, the affection of the respiratory organs being secondary. This opinion had been previously advanced by Stoll, and is also that advocated by Chambon in his work "*Des Maladies des Enfants*." Tourtelle likewise describes the disease as a catarrhal affection of the lungs and stomach (*affection pneumogastrique pituiteuse*). Millot entertains a somewhat similar opinion; he supposes, however, that the irritation of the stomach is secondary, and not so intense as that of the lungs and larynx. Opinions somewhat similar are maintained by Meltzer, Holdefreund, Butler, Klinge and Strack.

5th. The peculiar phenomena of the whooping-cough have been ascribed, by a few, to a physical or chemical irritant introduced into the larynx, either from without, or from the blood where it is engendered, or from the secretions of the respiratory organs. Under this head may be arranged the opinion of Linnæus, who referred it to the presence of minute insects; that of Sydenham, who imputed it to a subtle and irritating vapour in the blood, which affected the lungs; that of Bohme and Klinge, and also, partially, that of Rosen, who ascribed it to a peculiar miasm, acting chiefly on the nerves. Dr. Blaud, of the Hospital Beaucaire (*Revue Médicale*, March, 1831), considers the primary cause of whooping-cough to consist in an irritation, not inflammatory, of the mucous membrane of the bronchi, under which the glands and follicles of the membrane are caused to pour forth a specific secretion saturated with hydrochlorate of soda, the irritation caused by which, when it reaches the upper part of the trachea and larynx, throws the muscles of the glottis and of respiration into spasmodic action for its expulsion, in a manner exactly similar to any foreign body which may accidentally enter the larynx. This theory of the disease Mr. Streeter, of London, in a paper read before the Physical Society of Guy's Hospital, November, 1844, has adopted and zealously advocated, "as the one most consistent with the phenomena observable in the symptoms, pathology, and successful treatment of the disease."

Mr. Streeter regards, however, the primary affection of the bronchial membranes as inflammatory, and believes that it will be found, on careful observation, to be attended by more or less fever of an analogous character to that which attends the influenza.

The evidences upon which this gentleman rests the truth of this theory, are—"the

testimony of adults, who have been attacked by the disease, to the unusual and excessive saline taste of the expectoration so long as the paroxysms are severe—the resemblance of the expiratory efforts in the whooping-cough to those made by the excitatory system for the expulsion of a foreign body from the larynx—the very adequate explanation it affords, both of the extraordinary and spasmodic muscular actions which accompany the cough, and of its occurrence in paroxysms after intervals of uncertain duration—and, lastly, the key which it furnishes to the chaotic host of apparently opposite remedies that have obtained professional or popular reputation in its treatment. Of these remedies, we find one group adapted to lessen the original bronchial affections, and favour the expulsion of the offending mucus—as emetics, antimonials, and counter-irritants applied over the chest; another which acts by altering the quality of the secretion, as the alkaline carbonates, ammonia, and sulphuret of potass, so strongly recommended by Dr. Bland; another, by exciting a new action in the bronchial membrane, and, by constringing the vessels, to put a stop to the secretion, in a manner perfectly familiar to the physician in chronic bronchitis, and to the surgeon in purulent ophthalmia—as the super-acetate of lead, alum, common resin, tinc. cantharid., bals. copaiba, tar vapour, and even the inhalation of nitrous vapours, &c. Others, again, as musk, both native and artificial, camphor, arsenic, conium, belladonna, opium, and hydrocyanic acid, are more especially adapted for the nervous lesions; while antiphlogistic measures meet the inflammatory lesions of the third or complicated stage.

“When, he remarks, the convulsive whooping is fully established, it very commonly happens that symptoms which mark the third, or what may be appropriately termed the complicated stage, are developed, and continue to mark the varying and formidable phases of the disease which mostly attract attention in practice.” These tertiary phenomena usually manifest themselves “1st—as special lesions of the nervous and muscular systems—an exalted sensibility and morbidly susceptible state of the membrane of the larynx, the pharynx, the epiglottis, under which death from asphyxia may suddenly occur—morbid association of the action of the muscles of the glottis and respiration, in consequence of which the cough continues from mere habit, or is reproduced by the most trivial irritation of the air passages—reflex irritation often passing into inflammation of the nervous centres of the pneumogastric nerves, involving those of the phrenic nerves also; and, finally, these reflex affections may extend to the whole of the brain, or to the medulla oblongata and their meninges, and prove fatal by inducing general convulsions or hydrocephalus. All these, be it observed, are pathological conditions of the nervous system, which have been so constantly put forward in high relief, by the advocates of the nervous theory, as proximate causes of the disease itself.” A second class of tertiary phenomena include “the various congestive and inflammatory affections that result from the mechanical disturbance of respiration and circulation, and the extension of the primary bronchial inflammation to the trachea, larynx and pharynx, and to the tissues of the lungs themselves. Epistaxis, hæmoptysis, and fatal emphysema from extensive rupture of the air-cells, have occurred within my own experience, and have apparently resulted from the mechanical violence of the cough acting upon tissues previously weakened by disease.” A third class of tertiary phenomena “include fever and cachexia,” which are “present in individual cases in every conceivable variety of combination.” “In the absence of cerebral or pulmonary inflammation, the fever of the third stage is always asthenic, and often assumes a remittent type when the cachexia is of a marasmic character.”

For an account of the various lesions met with in the bodies of those who die of whooping-cough, the reader is referred to *Condie on Diseases of Children*, 4th ed.—C.]

The object of rational treatment in whooping-cough, supposing the disease to be simple, is to *keep* it simple: to keep it *mere* whooping-cough: to obviate serious inflammation, or mischief, in the chest and head: and, if possible, to mitigate the severity and shorten the duration of the fits of coughing. I have no notion that anything we can do in the beginning will materially abridge the duration of the complaint as it appears in its unmixed form. It *will*, I say, in all probability, run a certain course; and our business is to conduct it evenly and safely to the *end* of its course. For this purpose the diet must, in the first place, be regulated and reduced. The

child should be allowed to eat but little meat; it may be nourished as well, and more safely, upon milk, and unstimulating farinaceous matters. The bowels should be kept moderately open: and the patient in cold weather should be confined to the equable temperature of the house, or protected by warm clothing; and care should be taken to keep the internal temperature equable. The air of the bed-room should not be colder than that in which the child has passed the day. It should not be much above nor much below 60° Fahrenheit. You will find different persons employing and praising different plans of treatment; the object in all cases, however, being the same, viz., to *ward off inflammation*, and to *quiet irritation*. One very good plan, as I believe, is that of giving a grain, or a grain and a half, of ipecacuan, three or four times a day. This generally keeps the bowels sufficiently open, and seems to have a beneficial operation on the mucous membrane of the air-passages also. Or a few grains of rhubarb and of ipecacuan may be given every night: and if the cough be very troublesome and urgent, small opiates may be administered: syrup of poppies: or the extract of hyoscyamus: as many grains *per diem* as the child has years. There is a method recommended many years ago by a namesake of mine, which some people swear by. Sir William Watson's prescription was one grain of tartarized antimony and twenty drops of laudanum in an ounce of water. A tea-spoonful, or a dessert-spoonful, of that mixture was given every evening, or every other evening. I have heard the late Dr. Gooch say that his mother became famous as a village doctress by the help of that prescription. Fothergill's method was to give an emetic every day; or three or four times a week: and this plan is the more suitable when there is much wheezing, and the phlegm is brought up with difficulty. The best emetic substance in such cases is, doubtless, ipecacuan: and the best time for giving it is the evening. Mr. Pearson—who has had, I fancy, many imitators—used to prescribe, after the operation of an emetic, one drop of laudanum, five drops of ipecacuan wine, and two grains of carbonate of soda, in a draught, every fourth hour, for several days. Under some such treatment as this, the disease will reach its termination in from six to twelve weeks: and it frequently happens that when the child is quite well in all other respects, it still continues to *cough*. The cough would almost seem to be kept up by the mere influence of *habit*. Now, under these circumstances, change of air will often remove the cough, as if by magic: and the shower-bath, and iron in some shape, will sometimes succeed, if change of air be not practicable.

There is a great variety of medicines lauded as *specifics* against whooping-cough: but they are not to be trusted to. Many persons think highly of the prussic acid, as a remedy for the paroxysms of coughing. Others employ and praise the extract of belladonna. But these are gigantic remedies to employ upon such young subjects. If you give them at all, you must give them in very small quantities, and watch their effects. Dr. West thus records the result of his own experience in respect to the hydrocyanic acid, administered in minute doses—"This remedy sometimes exerts an almost magical influence on the cough, diminishing the frequency and severity of its paroxysms almost immediately; while in other cases it seems perfectly inert; and again in others, without at all diminishing the severity of the cough, it exerts its peculiar poisonous action on the system, so as to render its discontinuance advisable." The artificial tincture of musk is another substance which some have found useful. Three or four minims of it may be given in the outset, and the dose increased till some sensible effect is produced; and then the dose that has been so reached should be persisted in, without further augmentation. I have been assured, by a most intelligent practitioner, that he had got considerable credit by prescribing this medicine, after other persons, with other modes of management, had failed. Alum, in doses of three or four grains every four or six hours, has been given, with apparent benefit, when there has been much expectoration, and no fever. Digitalis, and cantharides, are other, and, I think, hazardous remedies. Safer drugs recommended, and, for aught I know, equally efficacious with these poisons, are cochineal, oil of amber, musk, camphor, and the meadow narcissus. Of late the carbonate of iron has been greatly commended by some of the continental physicians.

[Horst recommends the flowers of sulphur as almost a specific in whooping-cough. He gives it throughout the disease, from its onset until its termination. Schneider,

Roffy, Randhan, Riecken, and others, confine its use to the more advanced periods of the attack. Jadelot is said by Barthez and Rilliet to have derived the best effects from the sulphur as a remedy in whooping-cough, as well as in bronchitis unattended with fever. The sulphur is given to children between two and four years of age in the dose of from 6 to 8 grains, two or three times a day, and to older children in doses of from 15 to 20 grains, — in both cases the dose being gradually augmented.

Assafoetida will be found a very excellent remedy in the spasmodic stage of whooping-cough. Dr. Lombard states that he has often known frictions to the spine with the tincture of assafoetida of great service, and we have found a plaster of assafoetida applied to the chest promptly to relieve the cough, which is liable to remain after the more acute symptoms have subsided.

It is stated that M. Berger has found the plan of treating whooping-cough the most successful, to be; in the first stage, a moderate course of antiphlogistic remedies, purgatives, and repeated emetics of ipecacuanha in combination with tartar emetic. In the spasmodic stage, in which the indication is to quell the existing nervous irritation, being dissatisfied with the remedies ordinarily employed, he was induced to administer the nitrate of silver, from which he has obtained results singularly beneficial. He administers it in doses of from a sixteenth to a twelfth of a grain, at first three times, and afterwards four times a day. Of course the remedy should not be administered in cases where the state of the digestive organs contra-indicates its employment (*Annuaire de Thérapeutique*, 1846).

Dr. Golding Bird remarks (*Guy's Hospital Reports*, April, 1845), that, in the second or nervous stage of pertussis, after all inflammatory symptoms have subsided — and when, with a tolerably cool skin and clean tongue, the patient is still severely distressed by the more or less copious secretion of viscid mucus from the bronchi — each attempt to get rid of which produces the exhausting and characteristic cough — no remedy will be found to act so satisfactorily, or to give such marked and often rapid relief to the child as alum. He has not yet met with any other remedy which is equally efficacious. Dr. Bird generally gives the alum in doses of from two to six grains to children of from one to ten years of age, repeated every four or six hours. For a child of two or three years he employs generally the following formula: —

R Aluminis, gr. xxv; extr. conii, gr. xij; syrup. rhædos. ʒij; aq. anethi, ʒiij. m. Dose a medium sized spoonful, every sixth hour. Dr. B. has never met with any inconvenient stringent effects on the bowels during its exhibition; on the contrary, in more than one instance it produced, he says, diarrhœa. The only obvious effects resulting from its use were, diminished secretion, and of a less viscid mucus, with a marked diminution in the frequency and severity of the spasmodic paroxysms.

Dr. Davis, of London, (*Notes to Underwood*) is disposed to attach more importance to alum, as a remedy in whooping-cough, than to any other tonic or antispasmodic — others speak of it in equally favourable terms.

The belladonna has been strongly recommended as an almost unfailing remedy in the spasmodic stage of the disease by several of the German physicians. Dr. Wallor, of London, also, bears testimony to its efficacy, and we have in its favour the evidence of many distinguished practitioners in this country. Dr. Turnbull, of Philadelphia (*Trans. Penna. State Med. Soc.*, vol. v.), says that he has found nothing so prompt and efficacious in the second stage of whooping-cough as the extract of belladonna. He has employed it successfully in fifteen cases — four of which, of a most aggravated character, were in members of his own family — five males and ten females, of which the youngest was nine months and the oldest ten years of age. His mode of administering it was, after preparing the system by an antiphlogistic treatment, until the entire removal of fever and inflammation, as indicated by the reduced state of the pulse, and diminished heat of surface; there being, at the same time, no evidence of congestion of the brain or lungs present, to place the system fully under the influence of the belladonna — indicated by the dilated pupil, confused vision, and reddened skin). The medicine to be then intermitted until its effects pass off, when it should be again resumed in slightly increased doses, so as to keep the patient under its influence for several days, or until the paroxysms are fully checked, which will usually occur towards the sixth, eighth, or fourteenth day.

Dr. Turnbull directs the extract of belladonna to be triturated with water or simple syrup, and if to be kept for some time, and in warm weather, with the addition of a

little alcohol or spts. lavend. comp. The dose for a child, three months old, is one-sixteenth of a grain every three hours—for a child one year old, one-eighth of a grain, and so in proportion for other ages.—C.]

External applications are also much in fashion in the treatment of hooping-cough. Frictions to the spine and to the chest; and as counter-irritants, they probably are of some service. The tartarized antimony is the least innocent of these applications. It will often cause foul and very troublesome sores upon an adult skin: and till I am better advised than I am at present of its certain efficacy as a remedy for hooping-cough, no one (however authorized professionally *ludere corio humano*), should rub it upon a child of mine. Mothers are many of them fond of using Roche's Embrocation for the Hooping-cough. This (Dr. Paris tells us) consists of olive oil, mixed with half its quantity of the oils of cloves and of amber.

Such is the plan of management which you will do well to enforce—and such are the expedients which you may, if you please, make use of as auxiliaries to that plan—when the disease is *mere* hooping-cough. But when it becomes complicated with symptoms of inflammation within the chest, or with head symptoms—(and for such symptoms you must jealously watch)—then you must employ antiphlogistic remedies (in addition to the antiphlogistic regimen) adapted to the circumstances of the case. Now we have reason to believe that the *bronchi*, or the *lungs*, are affected with inflammation, when we find that the child has *fever*, and that there is *permanent dyspnœa* between the paroxysms of spasmodic cough. In such a case we must have recourse to the treatment required in such inflammation: leeches to the surface of the chest, tartar emetic, small doses of nitre, the warm bath, and blistering; and to these measures, modified and combined according to the particular emergency, it will be well to add small and repeated doses of mercury; of the hydrargyrum cum cretâ, or of calomel; the state of the bowels determining which. Some have recommended friction with the tartar emetic ointment upon the *chest* in such cases: but I have the same objection to it there, in patients so young, as upon the spine.

Permanent dyspnœa, unattended with fever, is more likely to depend upon collapse, than upon inflammation, of the pulmonary substance. Under such circumstances any active antiphlogistic measures would be out of place, and even hurtful. You must search therefore for auscultatory evidence as to the condition of the lungs, and adjust your treatment accordingly.

When any head symptoms come on, threatening hydrocephalus, or apoplexy,—such as squinting, convulsions, stupor—those remedies must be adopted which I endeavoured to describe to you when I spoke of those diseases; leeches to the head, cold applied there, purgatives, the warm bath; but, except in very young children, I believe there is more danger of fatal *pulmonary* changes in this disagreeable, and sometimes intractable disorder, than of cerebral mischief.

I might pass, by a very natural transition, from the consideration of hooping-cough, to that of *spasmodic asthma*. But this last complaint is found to exist in connexion with *various* organic changes within the chest, few of which have yet been treated of in these lectures. I shall therefore postpone what I have to say respecting asthma, till I have gone through some other thoracic diseases. And I now proceed to *pneumonia*, or inflammation of the *substance of the lungs*. Questions have been raised as to the precise part and texture in which the inflammation begins; and to these questions I may briefly advert as we go on; but I hold that in pneumonia *all the textures* composing the pulmonary substance in the part inflamed are involved in the inflammatory process.

Now of pneumonia it is especially true, that we ascertain its situation, its extent, and every step of its progress, by means of the ear. All the symptoms that give us the most sure information respecting the nature of the disease, its increase and aggravation on the one hand, or its abatement and diminution on the other, spring out of the actual changes wrought in the pulmonary substance itself; and these changes are disclosed to us by the method of auscultation. It is necessary, therefore, that you should understand, first of all, what those changes are which are produced by inflammation of the substance of the lungs: that you should know the morbid anatomy of pneumonia, as an indispensable groundwork for a knowledge of its pathology.

There are three well-marked, and very constant conditions of the lung, corresponding to different degrees and periods of its inflammation. I will describe them in succession, in the order in which they take place.

The first stage or condition is that of *engorgement*. All modern observers agree, I believe, both as to the nature and as to the name of this condition. The substance

Fig. 47.

Fig. 48.

Fig. 47.—Pleural surface of a portion of splenified lung, affected with typhoid pneumonia, from a female æt. 25, who died of typhoid fever. The lung closely resembled the spleen in consistency, was of a brownish red hue, interspersed with deep purple spots of an apoplectic character.

Fig. 48.—From a lung in rather an advanced stage of inflammatory engorgement, magnified 430 diameters. *a*. Fibrous tissue forming the walls of the air cells, distinct and enclosing a few granules; *b*. Very granular epithelial cells of bronchi and air vesicles; *c*. Small nucleated cells and exudation corpuscles, lying partly within, partly outside the air vesicles; *d*. Blood corpuscles. From Da Costa.

of the lung is gorged with blood, or bloody serum. It is of a dark red colour externally, and crepitates less under pressure than sound lung does. We feel that there is more liquid than air in its cells. It is heavier also than natural, and inelastic, and

Fig. 49.

Elements observed in lungs that had been in a state of chronic hyperæmia. *a*. Epithelial cells being transformed into granular cells; *b*. Flakes enclosing blood corpuscles which are irregular and of a yellowish colour; *c*. Blood-corpuscular cell, breaking up into a dark, reddish-brown pigment; *d*. Situation of freshly-formed pigment, in the tissue of the lung. From Da Costa.

retains, in some degree, the impression of the finger. When the engorged portion is cut, we find it red, and we see a great quantity of a reddish and frothy serum flow from it. Its cohesion is at the same time diminished: it is more easily torn; more, in that respect, like the spleen; and accordingly the term *splenization* of the lung has been given to this stage of its inflammation, as hepatization has to that which succeeds it. In this stage of engorgement the mucous membrane of the smaller bronchial ramifications is of a deep red colour. The portions most engorged, although their specific gravity is increased, will nevertheless almost always float on water.

Now it is necessary to caution you in the outset, against a very frequent source of fallacy in respect to this condition of inflammatory engorgement. Such a state of the pulmonary substance as I have been describing, you will meet with in half, at least, of the dead bodies which you may have to examine; and you must not necessarily infer therefrom that the persons deceased had *inflammation* of the lungs. There is almost always some degree of *mechanical* engorgement of the back part of the lungs; or of that part which has been undermost during the last hours of life, or after death; and the two kinds of engorgement can scarcely be distinguished from each other by their anatomical characters alone. Andral at one time held, indeed, that if the engorged part were more friable, more easily torn or broken down under pressure than natural, that was sufficient evidence of its inflammation; but he afterwards saw reason to change that opinion. We judge by the *situation* of the engorgement sometimes: if it be not in a depending part of the lungs, it is surely inflammatory. We judge also by the antecedent symptoms.

If the inflammation continue, the lung undergoes a further alteration, and presents the following characters. It is still red—externally and within; but it crepitates no longer under pressure; and it sinks in water: it contains in fact no air. Its cut surface presents sometimes a uniform red colour; sometimes a slightly mottled or variegated appearance, produced by an intermixture of specks of the black matter of the lung, and of the interlobular areolar tissue, which is less red than the other parts, and more than naturally obvious to the sight; but the spongy character of the organ is lost: it is evidently solid; and the cut surface very much resembles the cut surface of the liver. Hence Laennec, and after him most other writers, have applied to this altered condition of the lung the term *hepatization*. There still flows out, under pressure, from the surface, when a fresh incision is made, some red fluid, but

FIG. 50.

FIG. 51.

Fig. 50.—Appearance of lung-tissue in *red* hepatization. *a*. Air vesicles filled with inflammatory cells, some of which are nucleated; *b*. Concrete albuminoid masses; *c*. Granule cells. From *Da Costa*.

Fig. 51.—Lung in a state of red hepatization; the air-cells are filled with corpuscular fibrin or exudation-matter, and are surrounded by enlarged and congested vessels. Magnified twenty diameters. (Bayle's Granulations.) From a man æt. 66, who had double pneumonia.

it is much less in quantity than in the former degree; and it is not foamy; and if the surface be gently scraped with a scalpel, you may often perceive in the red fluid so collected, some traces of a thicker and yellower matter, the first indication of commencing suppuration. The hepatized lung is denser and more solid than before, but it is also more friable; more easily crushed and broken: and this results from the softening of the areolar tissue which holds its component parts together.

If you tear a portion of hepatized lung, and examine the torn surface with a magnifying glass, the pulmonary tissue will appear to be composed of a crowd of small red granulations, lying close to each other. These are, I presume, the air-vesicles clogged up, thickened, and made red, by the inflammation. As no air is contained in the lung in this stage of the inflammation, it follows that if the entire organ be involved in the disease, it will not sink down when the thorax is laid open; and will therefore appear to be increased in bulk. It is swelled, in fact,—just as other inflamed parts are swelled—by the congestion of its vessels, and by the effusion of blood, or of some of the constituent parts of the blood, into its hollows and interstices. The marks of the ribs are frequently visible on the surface of the distended lung. The texture of the lung in this condition is sometimes so rotten, that a moderate degree of pressure between the fingers will suffice to reduce it to a state of pulp; and this diminution of consistence has made Andral quarrel with the term *hepatization*: and he proposes to call this second stage of pneumonia, red softening, *ramollissement rouge*. All this is very unimportant, provided that you recollect the sense in which either nomenclature is employed. But as Laennec and Andral are both great authorities, and both have their disciples in this country, it is well that you should understand their language.

In a degree still further advanced, the pulmonary tissue, dense, solid, and impervious to air, as in the last stage, undergoes an alteration of colour: it presents a reddish yellow, or straw, or drab, or stone colour; or it is of a greyish hue, sometimes mottled with red, or with the black pulmonary matter. The little granulations which I just now mentioned are whitish or grey, instead of being red; and the texture of the lung is still more rotten and friable than before. It is full, in fact, of puriform matter, which is sometimes so abundant that it oozes out plentifully when incisions are made into the lung: or it may be made to exude by gentle pressure. The grey pus shows itself upon the cut surface in the form of minute drops. The more the pulmonary texture is soaked or drenched with this fluid, the softer and more friable it becomes. When crushed between the thumb and fingers, it is reduced to a yellowish grey pulp, exactly like the fluid itself only rather more consistent

FIG. 52.

FIG. 53.

FIG. 52.—Elements in peculiar “yellow” condensation, in a lung which was completely and uniformly infiltrated, magnified 480 diameters. *a*. Nucleated corpuscles and fibroid cells; *b*. Basis-substance in which many of the cells are imbedded. *From Da Costa*.

FIG. 53.—Microscopic characters of the contents of an air-vesicle in grey hepatization, consisting of granular matter, pus-corpuscles, exudation-cells, and cylindrical epithelium.

And by gently forcing the finger into any part of the parenchyma in this state, a small cavity may be made, which soon fills with pus, and which might readily be mistaken for a recently formed abscess.

Laennec has called this third stage of the process of inflammation in the lung, *grey hepatization*, or *purulent infiltration*. Andral denominates it *grey softening*—*ramollissement gris*. In fact, it consists in *diffused suppuration* of the pulmonary texture. And it is a very remarkable circumstance, and one which the researches of modern times have brought to light, that, in the lung, inflammation going on to suppuration, does not lead to the formation of a circumscribed abscess, as it does when it affects the areolar tissue, or the parenchymatous tissue, in other parts of the body. Abscess of the lung used to be spoken of as a very common thing; but it is

a very rare thing. In several hundred dissections of persons dead of pneumonia, made by Laennec during a space of more than twenty years, he only met with five or six collections of pus in the inflamed lung. Once only did he find a *large* abscess

FIG. 54.

Elements found in the lung in grey hepatization. *a.* Granular exudation corpuscles and free oil; *b.* Corpuscles when treated with ether; *c.* Fibrous tissue infiltrated with oil globules—fibres very indistinct; *d.* Small vessel, the walls of which are coated with granules; *e.* Pus corpuscles, rather dark and granular. *From Da Costa.*

of that sort. Once only has Andral seen a real abscess of the lung form as a consequence of pneumonia. You may find collections of pus in the lungs sometimes, occurring in connexion with the inflammation of veins. Several instances of that kind have happened very recently in patients who have died in the Middlesex Hospital. But these are not ordinary cases of pneumonia. I need scarcely caution you not to take tubercular vomicae and cavities, containing pus, for genuine abscesses of the lung. These, and the phlebitic deposits of pus, are not *exceptions* to the general statement: they arise from different forms of disease: and you will find a circumscribed collection of pus, surrounded by hepatized lung, as a consequence of common pneumonia, to be an exceedingly rare event.

Can we account for this in any way? I do not know that any satisfactory explanation of the fact has ever been offered. But I would submit to your consideration what has occurred to my mind on this subject. When I was speaking of inflammation in general, I pointed out to you the remarkable influence which the presence of atmospheric air in contact with the inflamed part has in accelerating, or determining, the event of suppuration. In a recent cut through the skin, the admission or exclusion of the air to the cut surface will make all the difference between the adhesive and the suppurative inflammation; and so in other cases which I then mentioned, and will not now trouble you by repeating. Now it seems to me that the same principle obtains in inflammation of the lung. First, there is an effusion of serum and blood, then of lymph and blood; but the air, passing into the surrounding sounder tissue, and penetrating for a time even the inflamed portion itself, causes the suppurative process to supersede the adhesive; and so no wall of circumvallation is formed by the coagulable lymph, as is the case in areolar tissue, which is not accessible by the air. Whether this be a sufficient explanation of the *fact* (all explanations being the resolving a given fact into a certain class of other facts more general and comprehensive), I say, whether it be a reasonable and satisfactory explanation, you will judge: at any rate it may serve to impress upon your memory that fact which it endeavours to elucidate.

Gangrene is sometimes, but very seldom, the result of acute inflammation of the lung. It is almost as uncommon as the formation of an abscess. Yet it certainly does now and then occur, as a consequence of acute inflammation of the pulmonary substance. It is somewhat more common (though under any shape rare) as an independent and primitive affection. Sometimes it occupies a large portion of the lung, and is uncircumscribed; and sometimes it is more limited. The colour of the part which has thus perished under inflammation, is dark, of a dirty olive, or greenish-brown colour. The gangrenous portion is moist and wet; sometimes of the consist-

ence of the engorged lung; more commonly softer, and even diffuent; and it stinks most abominably. This horrible odour is in truth, during life, the most distinctive character of gangrene of the lung. It sometimes renders the room in which the unhappy patient is lying, scarcely endurable. I should have stated before that the puriform infiltration of the third stage of pneumonia is attended with no fœtor.

There are some other points, connected with, or learned from investigating, the morbid anatomy of pneumonia, which I may as well take this opportunity of telling you, before we go on to consider the symptoms, physical and general, of that disease.

There are two lungs, just as there are two tonsils, and two eyes; and in the one case as well as in the others, inflammation may affect both organs at once, or it may affect one of them alone. Technically speaking, pneumonia may be either double or single. Again, the inflammation may occupy a part of one lung, or the whole of it: in other words, it may be partial or general; but it does not affect all parts, or both sides, indifferently or capriciously. In the first place, it is (why I know not) greatly more common on the right side of the body than on the left. I will give you some statistical statements collected by Andral, in respect to this point. Of one hundred and fifty-one cases of pneumonia, noticed at La Charité, ninety were of the right lung alone; thirty-eight only of the left alone; seventeen of both sides at once; and in six the situation was uncertain. He was at the pains of collecting the particulars of fifty-nine other examples of pneumonia, from different authors, so fully described as to leave no doubt about the nature and situation of the disease. Among these, the inflammation existed in the right lung alone in thirty-one patients; in the left alone in twenty; and on both sides at once in eight. Hence, taking both series of observations together, we have two hundred and ten cases of pneumonia; and there were one hundred and twenty-one in which the right side was solely the seat of the disease; fifty-eight in which the left; twenty-five in which the pneumonia was double; and six in which the seat was uncertain. So that, at this rate, pneumonia is more than twice as common on the right side as on the left; and does not occur on both sides together so often as once in eight times.

Again, with regard to that *part of the lung* which is most obnoxious to inflammation, there are remarkable differences. It is well known, and it is a very important fact in respect to diagnosis in some cases, that the lower lobes are more liable to inflammation than the upper. I speak, of course, of active idiopathic inflammation. But this circumstance, much insisted on by Laennec, and quite true in the main, has perhaps been somewhat exaggerated. I have not had leisure to frame any numerical statement of the cases that have come under my own observation, but the general impression which they have left upon my mind is in favour of the correctness of Laennec's statement — that pneumonia generally commences in the lower lobes, and spreads upwards frequently to the superior lobes. But I may adduce Andral's statistical representation in respect to this question also. Of eighty-eight cases of pneumonia, he found that the inflammation affected the inferior lobe forty-seven times, the superior lobe thirty, and the whole lung at once, eleven.

Inflammation of the bronchi constantly accompanies inflammation of the parenchyma. The mucous membrane presents a red colour both in the large and in the small branches of the air-passages. And when a single lobe is inflamed, it has been observed that the redness of the mucous membrane existed in those bronchial tubes alone which were distributed to that lobe. You may have bronchitis without pneumonia: but pneumonia without a corresponding extent of bronchitis, is perhaps never seen.

The majority of cases of pneumonia are attended also with a degree of inflammation of the investing membrane of the lung: there is some pleurisy. So frequently indeed is this the case, that certain writers, Andral among others, call the disease by the compound name of *pleuro-pneumonia*. However, pneumonia may and does sometimes occur without any concurrent pleurisy. Of the latter complaint I must speak by itself; and I merely notice now the frequent combination of the two—the occurrence of a slight degree and extent of pleuritis in most cases of pneumonia—that you may the better understand some of the general symptoms of pneumonia.

Now such being the changes which the lungs undergo when inflammation affects the pulmonary texture, we may next inquire what signals of its existence the inflammation holds out; and how far we, not having the power of *seeing* what is going on within the cavity of the thorax, may nevertheless ascertain the important processes which are there transacted.

If the ear be applied to the surface of the chest, with or without the intervention of the stethoscope, and the portion of lung subjacent to that surface happen to be in the first stage of inflammation, that of engorgement, what does the lung, so suffering, say? what audible notice does it give of its morbid condition? Why it speaks very plainly. You hear a peculiar crackling sound: the smallest and finest-possible kind of crepitation: which has been happily illustrated by saying that it resembles the multitudinous little crackling explosions made by salt when it is scattered over red-hot coals. Andral has another resemblance for it, and not a bad one; he says the noise is often like that which is produced by rumpling a very fine piece of parchment. Dr. Williams observes that a pretty correct idea of this sound may be obtained in a ready way, by rubbing between the finger and thumb a lock of one's own hair, close to the ear. Laennec calls this *crepitant rhonchus*: I would speak of it as *minute crepitation*; or the *crackling of pneumonia*. This may be heard in a very limited spot in the beginning. And what an important sound it is! "It is a direct symptom having immediate reference to the structure of the part. And (says Dr. Latham) if we consider what the part is, and what the disease; the part, the lungs, and the disease, inflammation: we cannot too highly value this single symptom (simple and mean as it may seem) which gives the earliest and surest intimation that such a disease has begun, as tends to disorganization, and the inevitable loss of life, unless quickly arrested by its counteracting remedy."

At first, when you catch the inflammation in its earliest stage, this minute crepitation, which announces *commencing* engorgement of the part, is heard mingling with the ordinary vesicular breathing; obscuring the natural sound, though it does not yet entirely cover it. But as the inflammation advances, the crackling becomes more and more pronounced, until at length it totally supersedes the natural sound. So long as the natural vesicular breathing overcomes the crackling, we may conclude that the inflammation is slight. But if the crackling should, in its turn, become predominant, if it should ultimately mask the murmur of respiration entirely, hat infallibly denotes the advance of the pneumonia, and teaches us that it tends to pass from the first into the second degree. But the crackling sound does not *long* remain in any part. As the case proceeds, the sound is less and less heard, and at length is not heard at all, in that spot; and it may be succeeded by one of two very different things. Its place may be taken by the natural respiratory murmur again. When this is so, it denotes the *resolution* of the inflammation. But the crackling may cease, and either no sound be heard at all in its stead, or another morbid sound which I shall presently describe: and this teaches us with absolute certainty, that the disease is growing more severe and serious; that the lung is becoming, or has become, *hepatized*.

Let us inquire, for a moment, before we go any further, what is the nature and where the seat of this minute crepitation, so characteristic of the commencement of pulmonary inflammation. With respect to its *seat*, I apprehend, there can be no question. It proceeds from the very smallest ramifications of the bronchi, and from the air-vesicles themselves. The common opinion is, and such, I confess, is mine, that the sound is the same in cause and kind, only different in degree, with the large and the small crepitation described in a previous lecture: that it results from the passage of air through liquid; from the formation and bursting in quick succession of a multitude of little air-bubbles. The bubbles are necessarily minute, for they are formed, and they explode, in very slender tubes. This is Andral's view of the matter. Laennec does not appear to have formed very clear notions on the subject. But a different explanation has been offered by a well-known and able writer on the auscultatory signs of disease, in this country: I mean Dr. C. J. B. Williams. He holds that the distended blood-vessels, and the interstitial serous effusion, press upon the minutest bronchial ramifications, and obstruct, without wholly preventing, the passage of the air through them: that these small tubes are lined by a viscid secretion, such as is expectorated, and such as I shall have to describe: that the sides of the tubes stick together in consequence of the presence of this viscid matter; and that it is the separation of these adhering sides by little portions of air which successively pass in and out, that gives rise to the characteristic sound. However, what it is important to remember is, that the crackling sound proceeds from the minutest divisions of the air-tubes, and from the ultimate vesicles of the lungs.

[Dr. Boling, of Alabama, describes "a fine mucous or erepitant rhoneus, seemingly seated in the larynx, loud enough to be heard distinctly at the distance of two or three feet from the patient, and so *persistent*, that it is not removable, or but momentarily, by any effort to expectorate which the patient may make, while at the same time there are present none of the signs of bronchitis or laryngitis." The patient seems indifferent to its presence. On applying the stethoscope just above the clavicles, it is found to proceed from the apex of the lung. This is *diagnostic of pneumonia of the apex of the lung*, one of the most dangerous forms of the disease.—*Amer. Jour. Med. Sciences*, July, 1847. — C.]

Sometimes, I say, when this crackling ceases, the ear applied to the corresponding surface of the chest, feels it heave up in inspiration, but catches no sound at all. Much more commonly, however, a *new* sound reaches the ear. It is not the vesicular rustle; it is not the minute crepitation: but a whiffing sound is audible, like that produced by blowing through a quill. Little gusts of air are puffed in and out; most distinct, often, at the termination of a slight cough or hem. This is the sound to which the term *bronchial respiration* has been given: and the name expresses well the fact. I mentioned before that in the healthy state we do not hear the air pass through the larger bronchi during inspiration and expiration: the sound doubtless is made, but it is obscured and hidden by the smooth rustle of the vesicular breathing, which comes from the spongy lung surrounding the large divisions of the bronchi, and intervening between them and the ear. But that spongy structure is now filled up. The hepatized lung admits air to pass through the larger bronchi, which are still patent, but it admits none into the vesicles and smaller tubes. It crepitates not when pressed between the thumb and finger; in fact, it is converted into a solid substance, and conducts the sound, in the living body, as any other solid substance might do: and therefore the whiffing, blowing, gusty sound of the breath, as it enters and departs from the larger bronchial tubes, which still remain open, is conveyed to the ear, and *bronchial respiration* is heard. At the same time, and in the same place, another auscultatory phenomenon generally arises, and admits of a similar explanation. The *voice* of the patient descends into the pervious bronchi, and is conveyed to the ear of the listener through the solid lung: and it is quite altered by that circumstance. The tone of it is modified; it sounds like the voice of one speaking through a tube. It is totally different from the same voice heard through the healthy lung at the corresponding point on the other side. It approaches in distinctness and quality, but it does not reach, the sound of the speaker's voice heard through a stethoscope placed over his trachea. A humming and muttering are audible, but the words are not distinctly articulated into the ear. It is hard to describe these things in words. Three minutes, at the bed-side of a patient in whom the bronchial breathing and the bronchial voice were tolerably well marked, would put you in possession of them for ever. They are striking sounds, requiring no fine tact to distinguish; and they are exceedingly informing sounds. But I must resume this subject when we meet again.

LECTURE LI.

Pneumonia continued: its general symptoms; pain, dyspnœa, delirium, cough, expectoration. Course of the disease. Prognosis. Treatment.

I WAS describing, at the close of the last lecture, the auscultatory signs which lead us to the knowledge that the inflamed lung, in a case of pneumonia, has passed from the first into the second stage of inflammation, and become solid, or hepatized. The altered condition of the organ gives rise to altered sounds. Instead of the vesicular breathing, which is the natural sound; or of the minute crepitation, which is

the sound belonging to the first stage of the inflammation; we either hear no sound at all, though we feel the chest heave up against our ear, or we hear what I described under the denomination of *bronchial respiration*; that is to say, a blowing sound, which is conveyed to the ear from the larger and still pervious branches of the bronchi, through the solid portion of lung around them, and through the solid walls of the chest. This is what the listener hears when the patient *breathes*. And when he speaks his *voice* is heard, much more resonant than is natural, much more resonant than in the corresponding spot on the opposite side of the chest, entering the same open air-tubes, and conducted to the ear by the dense and solid lung. We thus become acquainted with two entirely new sounds; sounds which are never heard in the healthy state of the lungs; *bronchial respiration*, and *bronchial voice*, or *bronchophony*: and you will do well to remember these two sounds, and to familiarize your ear with them; for they speak a most significant language in *other* pulmonary diseases, as well as in pneumonia.

But I say, sometimes we hear these morbid sounds, in the case in question, and sometimes we hear *no* sound at all during the breathing. How is that? Why the existence and degree of the bronchial respiration, and bronchial voice, vary according to the place and extent of the inflammation. These morbid sounds are most plainly marked, where the number and size of the bronchial tubes involved in the hepatization are the greater. They are most distinct, therefore, when the inflammation occupies the upper part of the lung; or the central parts, what are called the roots of the lungs: and when it extends thence to the surface: but when the lower portions alone are inflamed, or the inflammation is merely superficial or partial, they may not be heard at all. Again, if the hepatization should be so general and complete, as to prevent the chest, on the affected side, from expanding—you will, in that case, hear *no* bronchial *respiration*; for the air in the large bronchi must be stagnant. *Bronchophony*, however, may remain.

When we have the bronchial respiration, usually also we have dulness on percussion. The degree in which this is present will depend upon the circumstances of the case. If a portion of crepitant and permeable lung, even a thin portion, should intervene between the inflamed parts, and the walls of the chest, there will still be resonance on percussion, though it will not be exactly the natural resonance. If the hepatized part come close up to the ribs, the sound elicited by mediate percussion will be flat or dead. With all this, you will generally hear, in the sound lung, if the whole of the other be engaged in the inflammation;—or in those parts of the inflamed lung that are healthy;—you will hear, I say, *puerile respiration*: and this is a strong confirming symptom that a part of the breathing apparatus is spoiled, and that the remaining part is endeavouring to compensate for its deficiency.

Now this period in pneumonia, when no sound but bronchial breathing is audible during respiration, is a period of anxious and painful interest. We cannot tell whether the lung will revert gradually to its healthy state; or whether it is passing into the third stage, that of purulent infiltration. But taking first the most favourable of these two suppositions—what happens? Why, *there*, where for a while we heard nothing but bronchial respiration, a slight crepitation begins again to be distinguishable, especially at the end of each act of inspiration: gradually this increases in extent and intensity, and as it increases, the bronchial breathing, and the bronchial voice, become proportionally less distinct, because the texture of the lung is again becoming permeable by air, and therefore a worse conductor of sound. By degrees, the bronchial breathing and voice disappear altogether; the vesicular murmur begins again to mix with the crepitation, and at length supersedes it; and the lung is restored to its previous fitness for the purposes of respiration. The same symptoms therefore recur, over again, but in a reversed order; the *returning* crepitation is however coarser and larger, and less regularly diffused, than that of the *advancing* pneumonia:—and even when nothing is heard in the ordinary condition of the breathing, but the natural vesicular rustle, some crepitation is found for some little while to mingle with it towards the end of a full inspiration. Next, let us take the *worst* of the two suppositions. Auscultation has traced the disease, *through* its stage of engorgement, and *into* its stage of hepatization. Can it trace it further? I believe not with any certainty. We cannot say whether the lung remains in the state of hepatization (as it may remain), or whether it has passed into the third

stage. But at last, if the structure of the lung break down, and a portion of it be expectorated, air finds its way into the vacant spot, and gives rise to large gurgling crepitation. But other signs sometimes come to our aid when this state has been reached.

We often find, after death, the three degrees of pneumonia existing in different parts of the same lung; and therefore it is not to be wondered at that the different parts of the chest should during life yield sounds indicative of each of those degrees, or at least of the two first; minute crepitation *here*, bronchial breathing, and bronchophony, and dullness on percussion *there*, and in another spot, *no* sound at all, or on the other hand, *peurile* respiration.

Again, it must be confessed—and I am desirous of confessing it, for I am sure that the method of auscultation is brought into undeserved suspicion and disrepute by attempts made to assert its all-sufficiency in all cases—it must be confessed that in some instances, although pneumonia exists, the ear is able to collect nothing of it: nothing indicative of its situation, or of its extent, or even of its existence. The pulmonary expansion is clear, all over the thorax; nay, much more strong than is natural; and this circumstance justifies the belief that, from some cause or other, not *necessarily* from pneumonia, a portion of the lung has ceased to discharge its function, and the other portions have taken it up. This failure on the part of auscultation happens when the inflammation occupies a small portion only of the lung, and that portion is central, or deeply situated; at a distance from the walls of the chest.

Such are, then, the physical signs that accompany and reveal the successive changes of texture, destructive and reparatory, which take place in inflammation of the lungs. I do not know whether I have made them clear to you; but I know that no very long apprenticeship, if I may so speak, in the wards of a hospital, will be sufficient, with a little guidance, to render you master of them. There are indeed varieties, and modifications, and exceptions, which nothing but such an apprenticeship can ever teach you. Of these it would be idle and unprofitable for me here to speak: and I go on to consider the *general* signs of pneumonia; some of which, either in themselves, or in combination with the *physical* signs, are of no less importance than these.

In the majority of cases the commencement of inflammation of the lung is marked by shivering, followed by heat and increased frequency of pulse; in one word, by inflammatory fever: and at the same time, or presently after, a stitch in the side comes on, with cough, and a sense of oppression in the chest. In other instances, the disease steals on more insidiously, and succeeds to bronchitis; the inflammation appearing to propagate itself by little and little from the larger to the smaller bronchi, and ultimately to reach the air-vesicles themselves, and the interstitial textures; and this may be accomplished with or without the sharp pain or stitch in the side. At first the cough may be dry, but it soon is attended with a very characteristic sort of expectoration. The dyspnœa is sometimes but slight in the outset; sometimes considerable.

Apart, therefore, from the physical signs, we may say that the usual symptoms of pneumonia are pain, more or less severe, on one side of the chest; dyspnœa; cough; a peculiar expectoration; and fever.

[Dr. Boling, of Alabama, states that he has frequently observed in pneumonia, a symptom which he does not remember to have seen mentioned by any author, and which he has never noticed in any other disease. It consists in a deposition on the teeth, just along the margin of the gums, of a matter of different shades of colour, from a light orange to a dull vermilion, forming a line of about the sixteenth of an inch wide; deeper in tint at the gums and paler as it recedes, unlike the blue line in lead poisoning, and the line at the same part of a deeper shade than the rest of the gum, noticed by Dr. Theophilus Thompson in phthisis, (*London Lancet*, Sept., 1852). The deposit in pneumonia is upon the teeth; from which by careful wiping, it may in a great measure be removed, leaving, occasionally, a somewhat durable stain upon the enamel. Dr. Boling thinks that it is probably an exudation from the margin of the gums. It is not a deposition from the colouring matter of the bloody sputa, as it has been met with in cases unattended with the expectoration of bloody matter, even in cases of latent pneumonia, without cough or expectoration. In one instance, from the presence of this deposit alone, Dr. Boling was led to suspect the presence of the latter form of the disease, and actually detected it by auscultation. It is probable, Dr.

Boling remarks, that miasmatic poisoning may lead to the development of the deposit in question, inasmuch as, if it were of as frequent occurrence in other localities as in the malarial region in which he has observed it, it would have been noticed before. Still he does not recollect of ever meeting with it in any of the forms of uncomplicated miasmatic fever. Dr. Boling thinks that he has observed the presence of the deposit in at least one-third or one-fourth of the cases of pneumonia treated by him. The cases in which it occurs are generally severe; it is very rarely found in mild cases.—*American Journ. Med. Sci.*, July, 1852. — C.]

The pain in pneumonia appears to exist only in those cases in which the inflammation of the lung is accompanied by some degree of pleurisy. But these are the most numerous cases. It is most commonly experienced on a level with, or a little below, one or other breast; but it may exist in almost any other part of the thoracic parietes. Generally it is most severe at the beginning, declines by degrees, and ceases altogether for some time before the *pneumonia* ceases. It is aggravated by cough; by a full inspiration; often by sudden changes of posture; by pressure made upon the ribs or intercostal spaces; or by percussion of that part. For the same reason the patients cannot lie on the painful side. Andral declares that in all the individuals in whom he had noticed this pain, and who died, he found the pleura inflamed, and covered more or less with coagulable lymph; and, on the other hand, that he had constantly known the absence of pain coincide with a sound condition of the pleura. When there is no sharp pain, there is, however, some morbid sensation, of trouble, or tightness, or weight, or heat, on the affected side. He quotes, with approbation of its justness, the ancient observation respecting pneumonia — “*Affert plus periculi quam doloris.*” When I come to speak of pleurisy as a distinct and substantial affection, I shall revert to this pain.

It is, or it was, a common doctrine, that one of the general symptoms of pneumonia relates to the posture which the patient assumes; that the *decubitus*, to speak technically, is on the side affected. The truth, however, is what I have just now stated. The *breathing*, indeed, is more impeded when the patient lies on the sound than when on the diseased side; but in point of fact, patients labouring under this disease almost all lie upon their backs; the *decubitus* is dorsal. The disturbance of the breathing deserves some notice. In general it bears a direct proportion to the extent and severity of the inflammation. But there are many exceptions to this. In some persons the inflammation of even a small portion of one lung is attended with great constraint or hurry of the respiration. In others, who have a much larger portion of the pulmonary tissue intensely inflamed, the dyspnoea appears to be but slight. So that the degree of difficulty of breathing is not a *certain* measure of the seriousness, or rather of the extent and the degree, of the inflammation. It is probable, that if we knew of what kind was the ordinary breathing of the individuals thus differently affected, we should find that they whose respiration is generally indistinct, or noiseless, who do not seem to *want* all their lung for the purpose of breathing, would best bear to have a part of it inflamed; and *vice versâ*. *Ceteris paribus*, inflammation of the upper lobe causes greater dyspnoea than inflammation of the lower. I may observe further, with respect to dyspnoea in general, that you must not trust implicitly to what patients tell you on that head. They will often deny that they have any shortness of breath, when one may see them respiring with unnatural rapidity, or observe that in their discourse they pause between every three or four words to take breath.

However, the dyspnoea that occurs in pneumonia varies greatly both in degree and in kind in different cases. Sometimes it is so slight that the patient is not conscious of it, and the physician scarcely perceives it. Sometimes it is so extreme, that the patient, entirely regardless of what is going on about him, seems wholly occupied with respiring; is unable to lie down; can scarcely speak; his face becomes lividly red or pale, and is expressive of the utmost anxiety; his nostrils are expanded, his shoulders elevated, and all the muscles which are auxiliary to the diaphragm and intercostals, in full and evident action. In one word, the breathing is *laborious*. Now this is the sort of dyspnoea which I mentioned before as being characteristic of obstructive bronchitis. When it accompanies inflammation of the lungs, we may conclude that bronchitis is superadded to that disease. Sometimes again the respiratory movements are simply frequent and very short or shallow, as if the air were not able to penetrate

beyond the primary divisions of the bronchi. Dr. William Gairdner, who has closely studied these differences and their meanings, expresses them clearly in the following sentences:—The dyspnœa of *pure* pneumonia is a mere *acceleration* of the respiration, without any of the heaving or straining inspiration observed in bronchitis, or in cases where the two diseases are combined. So much is this the case, that I have repeatedly observed patients affected with a great extent of pneumonia in both lungs, and in whom the extreme lividity, and the respirations, numbering fifty or sixty in the minute, showed infallibly the amount to which the function of the lung was interfered with; and who nevertheless lay quietly in bed, breathing without any of the violent effort, or the disposition to assume the erect posture, so constantly accompanying the more dangerous forms of bronchitis. If this freedom from dyspnœa and laborious breathing be not uniformly characteristic of true pneumonia, it is because that disease comparatively seldom exists uncomplicated by some degree of bronchial affection.”

Between these states of extreme rapidity or extreme labour of breathing, and the slightest hurry or embarrassment of respiration, there are of course many degrees.

Delirium is a symptom which very frequently occurs in the course of an attack of pneumonia; and a very ugly symptom it is. It denotes that the due arterialization of the blood is largely interfered with by the pulmonary affection. It measures, in one sense, the quantity of mischief which is going on within the thorax: and it is a direct evidence that the pectoral mischief is telling, through the circulation of venous blood, upon the *brain*.

The cough, in pneumonia, has no particular character; and affords but little information. It does not usually take place in paroxysms; and its severity and frequency are not always proportioned to the intensity and extent of the inflammation. It is usually dry in the outset; but in a few hours it is accompanied by the expectoration of peculiar sputa, which constitute one of the most certain indications of the presence of pneumonia: and as this is a symptom which every one can easily recognise, I will describe this characteristic expectoration and endeavour to explain the cause of it.

The expectoration of pneumonia, when well marked, consists of transparent and tawny or rust-coloured sputa, uniting, in the vessel containing them, into one jelly-like and trembling mass: and of such viscidness that the vessel may be turned upside down, and strongly shaken, without their being detached from its bottom or sides. It cannot be said that when there is no such expectoration as this, there is no pneumonia: but it may be affirmed that where we do find such expectoration, there almost certainly we have pneumonia. At the outset of the disease, either nothing is spat up, or simply some bronchial mucus: but on the second or third day generally, the matters expectorated assume the characteristic appearance: *i. e.*, they come to be composed of mucus, intimately united and combined with blood. It is not that the sputa are *streaked* with blood, as often happens in *bronchitis*: nor have we the *unmixed* blood of *hæmoptysis*. But the blood and the mucus are amalgamated together: and in proportion to the quantity of the former, the sputa become of a yellow colour, or of the colour of rust, or of a decided red: and at the same time they become glutinous and tenacious; they adhere together, so as to form one transparent homogeneous mass. So long as this mass flows readily along the sides of the vessel when it is tilted, so long have we reason to *hope* (judging from that circumstance alone) that the inflammation of the lung does not pass its first degree. But, as I said before, the sputa often acquire an extraordinary degree of viscidness: so as no longer to separate themselves from the vessel when it is inverted: you cannot even shake them out. When this happens, we are obliged to *fear* that the pneumonia reaches its second degree. In fact, when the sputa become thus rusty and very viscid, the stricken chest almost always returns a duller sound, and the vesicular breathing is abolished, and bronchial respiration takes its place. The pneumonia is then at its acme; and the expectoration remains for some time stationary. At length, if the inflammation recede, the sputa become again less tenacious, less red or yellow, and more like the expectoration of mere catarrh. But if the disease go on from bad to worse, the rust-coloured sputa may continue to the end. Commonly there is *less* expectoration in that case, or even none at all. Not that the mucus ceases to be secreted, but that its excretion is no longer possible: either on account of its

extreme tenacity, or on account of the patient's debility. The sputa then accumulate in the bronchi, trachea, and larynx, in succession: they fill up the air-passages, and suffocate the patient. In some instances the expectoration, in the advanced stages of the disease, consists of a fluid having the consistence of gum-water, and of a brownish red colour: like (as Andral says) liquorice-water, or plum-juice. He states that the mere occurrence of this kind of expectoration has led him to announce the existence of the third stage of pneumonia; and that the subsequent examination of the dead body has seldom failed to justify his diagnosis. Sometimes again, during the third stage, very perfect pus is excreted.

That the colour of the sputa peculiar to pneumonia depends upon an intimate union of blood with the altered mucus, is perfectly obvious when that colour is deep. And even when this transparent mucus is yellow, you may satisfy yourselves by the following simple experiment that the source of the colour is the same, and that the yellowness does not result, as some have fancied, from an admixture of bile with the matter expectorated. If to water, rendered viscid by dissolving a certain quantity of gum in it, you add blood, drop by drop, you will obtain in succession, all the shades of colour that are presented by the pneumonic sputa: first a yellow tinge; then a tawny yellow which loses itself in a red, and comes to represent the colour of the rust of iron; and lastly an intense red. The sputa may, indeed, sometimes, but I believe *that* does not often happen, be coloured by bile: but bile is not the source of the yellowness which they assume in cases of pneumonia.

Sputa composed of very red mucus, indicate pneumonia less surely than such as are tawny. The very red masses, in which there is more blood than mucus, often belong to pulmonary apoplexy.

Although these rust or orange-coloured sputa are commonly present during the more active period of pneumonia, and, as far as my experience goes, are peculiar to that disease, you ought to be aware that they do not *constantly* accompany it. Sometimes the matters expectorated are like those of catarrh: and sometimes there is scarcely any expectoration at all.

When the pneumonia passes into gangrene—which I repeat is an exceedingly rare consequence of inflammation in that organ,—the expectoration becomes of a greenish, or reddish, or dirty grey colour; is more liquid, and exhales a foetid smell, resembling that which proceeds from gangrene of the external parts. So again the puriform expectoration which at length ensues in the rare cases of circumscribed abscess of the lung, from pneumonia, is horribly offensive.

I have now described, *seriatim*, the main symptoms, general and physical, which mark the existence and the progress of pneumonia. And in order to give you a just notion of each, I have spoken of them separately. But they *exist together*; and they must be *studied* together: and some will be found to confirm or to correct the indications that might be drawn from the others. I must briefly therefore run over the phenomena of the disease we have been considering, as, in most cases, it actually presents itself.

The first symptom felt is commonly pain in the side; which may or may not have been preceded by rigors. At the same time the breathing is constrained; and the patient coughs without expectorating. At this period, the ear may generally detect a slight degree of minute crepitation, which is not strong enough to mask entirely the vesicular rustle; and the stricken thorax still sounds well; and there is fever withal. This assemblage of phenomena constitutes the first period of the disease. From the second to the third day, new symptoms appear. The expectoration, hitherto absent, or merely catarrhal, becomes characteristic; being at first moderately viscid, and having a degree of colour proportioned to the variable quantity of blood which it contains. The minute crepitation increases, and drowns or supersedes the natural respiratory murmur: the clear sound produced by percussion begins to diminish on that side on which the crackling is heard and the pain is felt; and that pain is commonly less sharp than in the beginning. The dyspnoea augments, as is quite apparent from the short and frequent inspirations made by the patient. If the pain be acute, he cannot lie, on that account, on the side affected; neither can he place himself on the sound side, because in that position his respiration becomes more embarrassed; he remains therefore, almost constantly, lying upon his back.

In this condition of pneumonia, though the disease may be severe, the inflam-

mation is as yet in its primary stage. It often remains stationary for a while, and then recedes, and terminates by resolution. The dyspnœa diminishes, the slight dulness of sound disappears, the crackling is gradually displaced by the natural murmur of the pulmonary expansion, the sputa again become those of simple bronchitis, the fever subsides, and ceases; and all is well again.

At other times, instead of retrograding towards resolution, the pneumonia becomes more intense, or rather more extensive, without passing beyond its primary stage; and the patient may die while it is still in that stage. But this is unusual. Ordinarily, if the inflammatory engorgement do not cease by resolution, and the symptoms that announce it are exasperated, we must expect that the second stage will be established. And we may be certain that it exists when we observe the following phenomena:—the breathing becomes more and more constrained, short, accelerated; the speech ceases to be free; the patient can do no more than pronounce a few interrupted words in a panting manner. The sputa acquire such a degree of visciditv, that they can no longer be detached from the vessel by shaking it; the sound afforded by percussion, on the side affected, is decidedly dull; generally there still is crepitation, less fine in its character however than in the outset, without the admixture of any pure vesicular breathing; sometimes the crepitation ceases entirely, and either no sound at all is perceived by the ear, or, in the part where the percussion is dull, bronchial respiration is heard, and this is almost always accompanied with bronchophony. The patient continues to lie on his back.

In this degree of the disease the prognosis is always uncertain. The patient often sinks rapidly, and dies from apnœa. Yet even in this degree resolution may still take place. In that case the dulness on percussion diminishes; the bronchial breathing disappears; we hear afresh a coarse kind of crepitation, at first alone, then mixed with the natural respiratory murmur, which, in its turn, becomes alone audible. The sputa return to their catarrhal character. In the meanwhile the dyspnœa and fever diminish, and then cease entirely.

It would doubtless be very interesting to determine, in a given case, whether the lung of our patient was in the second or the third stage of inflammation. But there are no certain means for making this distinction. We may *guess* that the third stage is established if the face become exceedingly pale and corpse-like; we may be more confident of it if the prune-juice expectoration, or if puriform expectoration should occur; and our presumption will be strengthened if the disease have existed for a certain *time*. However, this last circumstance will not help us *much*; for sometimes the lung has been found to be in a state of suppuration on the fifth day of the disease, and sometimes it has been found still in a state of red hepatization after fifteen or twenty days.

Whether, when the lung has reached this third stage, it is still susceptible of repair, is a question which no one can answer. We have not the materials for its solution, inasmuch as we have no sure sign of the existence of this third stage during life. I should *think* that recovery from diffused suppuration of the lung is not possible. The rarer form of circumscribed abscess certainly is not of necessity fatal.

The *duration* of pneumonia may be laid, upon an average, at ten days, or a fortnight. In a table collected by Andral for another purpose, viz., to determine whether there were any fixed *critical* days in respect to the termination of the disease (a question which I shall not now discuss), the duration, in 112 cases, varied from four days to six weeks. But one only was thus protracted; 23 cases lasted each seven days; and only 15 of the 112 instances continued longer than a fortnight.

I have very little to add to what I have stated already of the morbid anatomy of pneumonia. Of the changes which the *lung itself* undergoes you are now I hope fully apprized. The pleurisy, which often attends the disease, is seldom accompanied by much effusion; indeed, when the whole of one lung is solidified by inflammation, it fills the cavity of the pleura, and *prevents* much effusion. The heart is found to be in that condition which I formerly described to you, as being both a consequence and an index of death by apnœa. Its right cavities especially are distended by black coagulated blood; and a remarkable degree of venous congestion is frequently met with in the liver, and spleen, and intestines. The amount of this varies according as the process of dissolution—what the French call the *agonv*—has been more or less protracted, and the breathing more or less difficult.

Neither need I enter upon any formal discussion of the *causes* of pneumonia. Sometimes *no* cause can be traced; often the disease is clearly the consequence of exposure to cold: especially under those circumstances which were formerly described as aiding the injurious operation of cold upon the human body. Why, in one person, such exposure causes peritonitis, in another pleurisy, and in a third inflammation of the substance of the lungs, we can give no satisfactory account.

It remains, then, only that I should speak, first of the *prognosis*, and secondly of the *treatment*, of pneumonia; and of the first of these matters, of the prognosis, I have already, incidentally, told you nearly all that is made out, or worth knowing. It is almost superfluous to say that the first degree of the disease is less dangerous than the second, and the second than the third. There is no doubt that pulmonary inflammation may still undergo resolution, although a great part of one lung should be hepatized; but there are no facts which prove—indeed there is no possibility of proving—that the lung may recover from the state of purulent infiltration—the third degree.

Something will depend upon the *extent* of the inflammation; I mean that pneumonia in the first degree and of great extent, is generally as serious as pneumonia in the second degree but much more circumscribed. Inflammation of the upper lobes is also more perilous than inflammation, to the same extent and degree, of the lower.

Of the *general* symptoms, those which we learn independently of auscultation, the *respiration*, as a prognostic sign, is the most important. Laboured breathing, and shallow and frequent breathing, are both of them symptoms of bad omen. We get less help from the state of the *pulse*. If, however, a feeble pulse go along with great difficulty of breathing, and if it do not develop itself under venæsection, we must conclude that the case is a serious one, and deduce an unfavourable prognosis. The supervention of *delirium* is also a discouraging circumstance. You will have inferred already the information which may be gleaned from the character of the expectoration, in respect to the probable issue of the disease. Great viscidities of the sputa, and a deep rusty colour, announce intensity of inflammation: their return to the catarrhal condition indicates that resolution is going on. Watery and brownish sputa, more or less like plum-juice, should induce us to suspect suppuration of the lung, and are therefore of evil augury.

To dictate the treatment of pneumonia is not an easy task. It may sound like a paradox, but concerning this disease I believe it to be true, that the very perfection of modern diagnosis has helped to bring uncertainty and vacillation into our practice. Inflammations of the lung, which might escape all other modes of investigation, reveal themselves infallibly to the ear. By the same sense we learn, as surely, that many of these otherwise latent inflammations run their course without any great commotion of the general system, whether they kill, or whether they pass gradually away. These forms of pneumonia neither require, nor would they endure, nor have they had addressed to them, so far as I am aware, the active measures which, prior to the use of auscultation, were enjoined as proper in unmixed inflammations of the lungs. On the contrary, the current has set, and is setting (too strongly I conceive), in the opposite direction. A most distinguished French author, M. Louis, has endeavoured to show that venæsection has not much control over the progress or the issue of pneumonia in any of its forms: and in our own country that doctrine has been adopted by at least one very accomplished physician—adopted and extended, for Dr. Hughes Bennett maintains that antiphlogistic remedies in general, and blood-letting in particular, are unsuitable, and even hurtful, in all acute inflammations. I believe that I might ascribe similar opinions to physicians and surgeons of eminence, in this town.

Now, although this, in my humble judgment, is a mistake, although venæsection and tartar emetic are still, in my opinion, the proper remedies for the early stages of those flagrant forms of thoracic inflammation with which our predecessors were dealing when on the basis of experience they put these remedies in force, and recommended them to others, I do not profess myself a partisan of any extreme views in the matter, either theoretically or practically. My own experience teaches me that such flagrant and sthenic forms of pneumonia have become very rare among us. Years have passed by since I have met with any instance of that disease which has required

phlebotomy. I may say much the same of inflammatory diseases in general. They have all, as I firmly believe, been less tolerant of blood-letting since the cholera first swept over this country in 1832. I may be fanciful, but I think that great epidemics, such as those of cholera and of influenza, leave traces of their operation upon the health and vitality of a community, long after they have ceased to prevail as epidemics. But while, upon these great questions, the mind of the profession remains unsettled and even divided, I would have you be cautious observers, rather than eager disciples. More than once or twice I have admonished you that, in prescribing, you must not be guided by the mere *name* of a disease: in this particular instance you must not be guided even by the *thing*, *pneumonia itself*, as disclosed by the evidence of auscultation. The constitutional symptoms must direct the treatment, while the local symptoms identify the disease. If, with the physical signs of pulmonary inflammation, in a patient who was previously strong and healthy, there be conjoined high fever, a hot and dry skin, a hard, firm pulse, pain of the chest, and restricted breathing—and especially if you meet with such symptoms in their early course, accompanying the first stage of the disorder, the stage of engorgement, before the spongy texture of the lung has been obliterated—then you may bleed your patient, not only, as I believe, without harming him, but to his great benefit and safety. And the bleeding should be carried to that point at which some sensible impression is made upon the symptoms; until the *pulse* becomes *softer*; or if it were contracted, until it becomes *fuller*; until the sensation of painful *constriction* is abated, and the *dyspnœa* relieved; or until syncope appears to be at hand. Whether the venæsection should be repeated, must be determined by the subsequent progress and aspect of the case. As an auxiliary to the lancet, and in less severe cases as a substitute for it, I should advise abstraction of blood from the surface of the chest by means of cupping-glasses, or of leeches. I scarcely need say that the antiphlogistic regimen should be at the same time enforced; that the patient must keep his bed; and that all superfluous exertion of his lungs in speaking must be forbidden.

When the inflammation has advanced into the second stage, we cannot expect that the removal of blood will have any direct influence upon the inflamed and solid parts; but even then, if duly moderated, and under the guidance of the constitutional symptoms, it may be serviceable, by diminishing the force of the heart and arteries, and so tending to prevent the extension of the inflammatory process; by lessening the whole quantity of blood circulating through those portions of the lung which are still pervious, and thus relieving dyspnœa; and by putting the system at large into the condition most favourable for the re-absorption of the lymph by which the air-tubes and vesicles of the affected parts have been blocked up.

But a time arrives when bleeding is no longer of use, or when it is positively hurtful: when it ceases to have any good influence on the local disease, and has an injurious influence on the whole system; reducing the patient's strength, and incapacitating him for bringing up, and ridding his lungs of, the tenacious mucus exhaled by the bronchial membrane. This is what takes place in those cases in which the expectoration is said to be *stopped* by a bleeding. We want some remedy, therefore, to aid the blood-letting, or to employ alone when the abstraction of blood is no longer expedient, or has been inexpedient from the first: and we have two such, in *tartarized antimony*, and in *mercury*. The tartar emetic plan I believe to be the best adapted to the first degree of the inflammation—to that of engorgement; and the mercurial plan to the second—to that of hepatization.

I need not tell you that the tartarized antimony is not given in this disorder with the object of producing vomiting. It is a very curious thing that although, when administered in a considerable dose, its first effect is usually sickness, followed perhaps by purging, a repetition of the same dose is, in the majority of cases, at length borne without any further vomiting. The stomach comes to *tolerate* the medicine, as our continental brethren say; and then its beneficial influence upon the disease is no less marked than when nausea and retching take place. Some patients do not vomit at all; others, the majority in fact, vomit two or three times, and then *tolerance* is established. If the sickness and purging go on, they may be checked by adding a few drops of laudanum to each dose. Dr. Thomas Davis, who had tried this remedy largely, and, as he tells us, with great success, gives the following as his own plan of administering it; and perhaps it is as good as any. After the requisite bleeding, he

begins with one-third of a grain of tartar emetic in half a wine-glassful of water, with a few drops of laudanum or syrup of poppies. Two doses of this strength he gives at the interval of one hour from each other. He then, if the patient do not vomit, omits the opium, but continues it if he do, doubling, however, the quantity of the tartar emetic, giving two-thirds of a grain for two successive hours; and in this way he goes on, adding every two hours a third of a grain, until he reaches two grains hourly. This last quantity he has not exceeded, and he says that he has continued it for many days without producing any injurious consequences.

Under this plan of treatment the symptoms will often undergo a marked change for the better, in three or four hours. Sometimes, however, the relief is not conspicuous for twenty-four or even for thirty-six hours. He states, and this is accordant with my own experience of the remedy, that the tartar emetic always acts best when it produces no effect except upon the inflammation itself; *i. e.*, when it does not cause vomiting, or purging, or a general depression of the powers of the system. This is an important practical remark, because many persons have supposed that it subdues the disease only when it previously gives rise to these symptoms. I consider this testimony of Dr. Davis's, to the power of the tartarized antimony in controlling inflammation of the lungs, the more valuable, because he informs us, that before he had occasion to see its admirable effects in the first stage of pneumonia, he had been in the habit of trusting to the free use of mercury, after due depletion.

When the dyspnœa has been appeased by antimony thus exhibited, the medicine may be intermitted; and if the inflammation show any disposition to rekindle, it must be again be repressed by a repetition of the tartar emetic.

When, however, the inflammation has reached the second stage, that of solidification, mercury is more worthy of confidence, in my opinion, than tartarized antimony. And I have little or nothing to add to what I formerly said in respect of the mode in which it ought to be administered. The object of giving it is to make the gums tender; and it is expedient to do this as speedily as may be. Small doses of calomel repeated at short intervals—a grain every hour, or two grains every two hours, or three grains every three hours—combined with so much of laudanum or of opium as may be requisite to prevent it from running off by the bowels—offer the most certain way of accomplishing our object. If the bowels prove irritable under the calomel—blue pill, or the hydrargyrum cum cretâ, may be substituted for it with advantage: and if the internal use of mercury be anyhow contra-indicated, or if it appear slow in producing its specific effect, the linimentum hydrargyri may be rubbed in, or the strong mercurial ointment.

Many persons, I am persuaded, are saved by treatment of this kind, pushed to slight ptyalism: the effusion of lymph, tending to spoil the texture of the lung, is arrested; and the lymph already effused begins to be again absorbed: and the ease and comfort of the patient, as well as the alteration for the better of the physical signs, attest the healing qualities of the remedy.

After the inflamed lung has become solid and impermeable, the treatment must still be regulated rather by the state of the system at large, than by the actual or presumed condition of the lung: we still look for guidance more to the general symptoms, than to the physical signs. If the pulse continue steady and firm, wait patiently the effect of the mercury. But when sunken features, a pallid face, coldness of the surface or extremities, a tendency to delirium, and (above all) a feeble or irregular pulse, proclaim that the vital powers are giving way, it will be requisite, as in other cases where death is threatened by asthenia, to administer cordial and stimulant medicines; the carbonate of ammonia in a decoction of seneka; wine: and to feed the patient well on milk, or beef-tea.

Among what may be called the routine remedies of pneumonia, we must rank counter-irritation by means of blisters. And I believe that they are often applied to the chest much too early in such cases. In the outset, while there is yet considerable fever present, they add to the irritation, and distress the patient: and probably tend to aggravate the existing inflammation. But when the fever is no longer high, and the skin no longer burning, though the expectoration is still difficult, the dyspnœa considerable, and a sensation of pain, or tightness, or oppression, is experienced in the chest, then a large blister is often productive of very sensible benefit; but it should be a large one. The patient should have a waistcoat almost, or at any rate a

breast-plate, of blistering plaster. I have never seen such good effects from placing blisters upon distant parts in this disease, upon the thighs or arms for instance, as would lead me to plague the patient with them in those situations.

Purgatives are of less certain value in pneumonia than in many other inflammatory diseases: and less, especially, than in cerebral inflammation. Still it will always be right to give an active aperient at the outset; and afterwards to take care that the bowels be unloaded at least once every day. A continued drain by purgation would not consist at all with the mercurial plan, which promises to be most useful when the inflammation has already reached the stage of hepatization.

This, then, is an outline of the treatment which is most likely to save the life of those who are affected with acute idiopathic pneumonia. Different cases will require different modifications of it; for which, I repeat, no particular rules can be laid down.

All that I have hitherto been saying relates to *acute* pneumonia, occurring in a previously healthy person. But pneumonia, having that character, and so occurring, is (I repeat) a much less common disorder than most persons appear to suppose, or than I formerly thought it to be. I have been surprised to find how few cases of pure idiopathic inflammation of the lungs present themselves among my hospital patients. Five or six in the year are as many as I see there. Intercurrent pneumonia, however,—pneumonia engrafted upon some other pre-existing disease,—is abundantly frequent; and requires, in general, a much less vigorous, and more wary plan of treatment. Inflammation of the pulmonary substance is apt to supervene insidiously upon various disorders which are of every-day occurrence: upon bronchitis; upon phthisis; upon disease of the heart; and upon fevers, especially the exanthematous fevers. In these cases, while the physical signs are necessarily the same as in the unmixed acute disease, the general symptoms are often but slightly pronounced. During the progress of continued fever of a low type, inflammation may steal upon the lung, and run quickly through all its stages, and spoil the organ irrecoverably, without giving any notice of its presence: unless, indeed, you suspect it, and search for it with your ear. The pneumonia is said, in such cases, to be *latent*. It seldom needs, the associated disorder would seldom bear, any active depletion. Much benefit often follows the abstraction of small quantities of blood, but they should be taken from the surface of the chest by the cupping-glass, and not by the lancet from the arm; and it is often good practice thus to aim at reducing the local mischief with one hand, while with the other we support the patient's strength by means of ammonia, wine, and nourishing broths. Blisters are also of service: more so than in the sthenic forms of pure pneumonia; and they may be applied at an earlier period. In conjunction with these remedies I should advise the cautious employment of mercury.

When the convalescence from acute pneumonia is decided, and real, it is shorter than might have been supposed. From the period when the pulmonary inflammation is fairly over, the strength returns with unexpected facility, even though large bleedings have been practised and repeated. But we have to guard, more perhaps in this disease than in most others, against false or merely apparent convalescences. A patient can never be pronounced perfectly secure so long as any trace of crepitation remains in the affected lung, and this may often continue long: nay, it not unfrequently ceases only upon the supervention of another more surely fatal, though less rapid a disorder—viz., tubercular consumption; of which, however, I must treat as a distinct disease.

[PNEUMONIA IN CHILDREN.—Pneumonia is a very frequent disease of childhood; and as it is then marked by some very important modifications in its general characters and results, it demands a separate consideration.

The inflammation may be confined to the minute lobules of the lung, or it may attack the pulmonary lobes. The first constituting lobular, and the second lobar pneumonia. In both forms of the disease the inflammation may be confined to a small portion of one lung, or extend to nearly the whole of one or both.

In very young children the symptoms of pneumonia, particularly at the commencement of the attack, are very obscure, and even when more distinctly marked, they differ but little from those of bronchitis.

In infants the attack is very generally preceded by symptoms of a mild bronchitis, to which there usually succeeds a chill, differing in its severity and duration in different

cases; this is followed by increased heat and dryness of the surface, increased frequency of pulse, accelerated respiration, dyspnoea, and a short dry cough. These symptoms quickly augment in intensity—the lips become of a bright red, the tongue of a florid hue, and somewhat dry, and coated along its centre with a thick white fur. Often there is from the commencement of the attack vomiting, and, in young children, diarrhoea. In many cases there is considerable agitation and anxiety, in others decided drowsiness, and more rarely convulsions; these are sometimes violent and repeated, and often followed by an entire loss of consciousness. Convulsions, according to the observations of Rilliet and Barthez, are confined to cases occurring in young infants, where the inflammation is seated at the summit of the lungs.

In infants at the breast, in the early period of the attack, the breathing is no longer affected solely through the nose, but the little patient lies with the mouth partly open, and drawing in the air through it. The tongue becomes in consequence preternaturally dry, and the child sucks by starts—seizing the nipple with eagerness, sucking for a few moments with greediness, and then suddenly dropping the nipple, and in most instances commencing to cry or moan.

The inspiration in children affected with pneumonia is marked by a peculiar abruptness, occurring suddenly before expiration is completed, and with a more or less dilatation of the nostrils.

The frequency of the respiration is not always in proportion to the violence of the attack, and does not always increase with the progress of the disease. When pneumonia occurs in the course of chronic enteritis, there is often either a very slight or no acceleration of respiration; it may, also, be masked by an accompanying affection of the abdominal organs or of the brain. In cases of broncho-pneumonia, the dyspnoea is often so intense as to threaten suffocation. The dyspnoea is always proportionate to the violence and extent of the pulmonary inflammation, and augments with the progress of the disease. It is often attended with great anxiety, and a sense of impending suffocation which renders a recumbent posture insupportable.

The cough is at first frequent, short, dry, and painful, but soon becomes moist; when expectoration occurs, which is seldom the case in young children, it is, at first, slight, and consists of a whitish, viscid mucus, which becomes subsequently reddish. It is rarely, however, rust coloured. As the cough becomes more moist, it gradually declines in violence until towards the eighth or ninth day, when it rapidly diminishes, and finally disappears. When, however, the pneumonia becomes more diffused, or occurs in the course of some acute affection, and in children not much debilitated, the cough is very frequent and intense, and is rarely attended with a free expectoration. The attacks of pneumonia that so frequently occur in the course of chronic enteritis, are seldom attended with much cough—occasionally, indeed, it is entirely absent. There is seldom any very decided pain of the chest—when present, it is generally acute, though occasionally dull, and is usually experienced at the anterior margin of the axilla—it is augmented by the cough, and often disappears long before the *other* symptoms.

The disease in these cases is so often destitute of leading symptoms, that its existence might be overlooked, were it not for the physical signs revealed by auscultation—the skin is pale and cool, the pulse small, and the face and extremities oedematous.

In young children, or those under six years of age, pneumonia is frequently preceded by extensive bronchial inflammation. The inflammation of the lungs, which is probably produced by the extension of the inflammation from the extreme branches of the bronchi to the preliminary tissue, often comes on so gradually, that it is impossible to fix, in most cases, the exact date of its occurrence. Occasionally, at the period the pneumonia supervenes, there is a well-marked accession of fever and dyspnoea, and an aggravation of all the symptoms. The febrile symptoms are less than in the other forms of the disease, but the dyspnoea and distress are usually greater, and the face presents from the first a more livid hue. The cough is less hard, but often occurs in paroxysms which greatly distress the patient; the respiration is more hurried and irregular; the irregularity coming on at an earlier period. Head symptoms are more frequent, the patient's rest is disturbed, and he often mutters in his sleep, and has far more restlessness and jactitation when awake. Convulsions and coma more frequently precede death, which occurs at an earlier period than in the other forms of pneumonia.

Pneumonia in children is generally attended with loss of appetite and increased thirst, and a torpid state of the bowels; when the disease, however, is complicated with enteritis, profuse diarrhœa may be present throughout the attack. In these cases furunculi or ecchymoses occasionally cover the skin, while the blistered surfaces are liable to become ulcerated.

In favourable cases of primitive bronchitis, the acceleration of pulse and respiration attain their greatest intensity generally by the end of the fourth, fifth, or seventh day, or, at the farthest, by the ninth day: when the heat of the skin and the frequency of the pulse diminish, respiration becomes slower, and the inspiratory movement is unattended with dilatation of the nostrils. The cough becomes more free and moist, the fever quickly disappears, the face becomes paler, and the expression of the countenance more natural. The respiration finally assumes its normal rhythm, the cough rapidly diminishes, and in a few days convalescence is fully established.

In the more severe and unfavourable cases, there is intense dyspnœa from the very commencement of the attack—intense anxiety, a pallid hue of the face, with a violet tinge of the lips and summits of the cheeks, an extremely small, rapid pulse, and a frequent, short, dry, painful cough. The general symptoms continue to augment in violence, and death may occur on the third or fourth day. In other cases, the symptoms, from the beginning of the attack, are less intense, and do not increase in severity after the fifth or sixth day, but remain, as it were, perfectly stationary. Soon, however, in addition to the cough and dyspnœa, there occur pallor of the face, great emaciation, and constant diarrhœa; and, at the termination of from three to four weeks, the patient, being reduced to a state of the utmost debility, expires. In other cases, again, after all the prominent symptoms have declined, and a speedy convalescence is anticipated, from some accidental cause, the inflammatory action is re-excited in the lungs, the dyspnœa, cough, acceleration of the pulse, and fever, return with increased violence, and death speedily ensues. The fatal termination may also be hastened by the occurrence of pleurisy, measles, gangrene of the mouth, &c.

Acute pneumonia, occurring in the course of some other acute disease, is generally of rapid progress, and terminates either in health or fatally, within a few days.

The physical signs of pneumonia, occurring in children, are of primary importance. By them alone, in many cases, can a correct diagnosis be established—while it is only by them, also, that the extent and progress of the local disease can be determined.

In simple primitive pneumonia of children, if of the lobar form, there are present, from the very commencement of the attack, crepitant ronchi, and often bronchial respiration on one side the thorax towards its base. The crepitus is generally larger than in adults. If for a short time it cannot be heard, it may be generally reproduced by causing the child to cough, when it is again to be distinguished, in the strong inspiration which succeeds the cough, the sound resembling the cracking of a whip.

In the lobular form of pneumonia, the subcrepitant ronchi are more generally diffused, while the bronchial respiration is seldom heard. The extent of the latter increases with the progress of the inflammation, while the ronchi decrease. When the acceleration of the respiration and pulse has attained its maximum, the bronchial breathing is very audible, and is accompanied with bronchophony, or with a resonance of the voice and extensive dullness of the chest. As the general symptoms decline, and the cough becomes more moist, the subcrepitant ronchi are very abundant, and the resonance of the voice extends over a greater space; the bronchial breathing continues, but the dullness of the chest diminishes. Even after convalescence is established, a slight prolongation, as well as a different resonance of the voice, is still perceptible. The respiration continues feeble for several days, and only slowly recovers its proper vesicular tones.

In more violent cases, humid ronchi are heard throughout the chest, intermixed with others of a drier character, or with bronchial expiration and a diffused resonance of the voice. Bronchial breathing is always a very grave sign. In eleven out of twenty cases in which it was detected by Dr. West of London, the disease had a fatal termination.

The mucous rhonchus is heard in most cases of broncho-pneumonia in children, and in cases of lobar pneumonia, in the neighbourhood of the subcrepitant rhonchus, and occasionally where distinct bronchial respiration exists. It often persists for a long time after every other sign of disease has disappeared.

In the lobular pneumonia of young children, the physical signs are at first limited to the mucous and subcrepitant ronchi, dependent upon the increased secretion of mucus in the bronchi. The subcrepitant ronchi are frequently continued throughout the attack, being often the only stethoscopic sign present. They are rarely replaced by the fine crepitant ronchi, as in the pneumonia of adults. Bronchial respiration becomes developed when induration has extended to a considerable portion of the texture of the lungs. It is chiefly heard at the upper and middle portions of their posterior parts—it is rarely heard in the lower lobe, from the comparative smallness of the bronchi, and their early obliteration by the progress of the inflammation. The respiratory sounds are very peculiar—the inspiratory murmur, in place of being full and expansive, as in a healthy child, is short, obscure, and almost without the vesicular murmur, and may or may not be accompanied with the mucous or subcrepitant ronchus; the expiration is rarely distinct, unless the bronchial respiration is fully developed, when it is usually louder than the inspiration. The sounds indicative of inflammation of the texture of the lung are often entirely obscured by the mucous ronchi of bronchitis.

The anatomical lesions in the pneumonia of children differ very materially, according as the inflammation is lobular or lobar, and according to the period of the disease when death takes place.

In lobular pneumonia the lung is usually soft and flaccid, of a mottled appearance externally; patches of a deep red or violet colour, generally distinctly circumscribed, of a circular or oval form, hard to the touch, and slightly projecting, being interspersed in the midst of the natural greyish-red tint. They are commonly situated at the inferior edge of the lung, but may occupy other portions of its surface. The part occupied by these patches does not collapse upon the chest being opened.

In some cases this marbled appearance of the lung is absent; but spots of induration, more or less deeply seated, may be detected by the fingers, giving to the lung an uneven or knotted feel.

The same marbled appearance is presented by a section of the lung. The dark patches are more or less accurately circumscribed in the first stage of the disease; they are firmer than the surrounding tissue, swim when thrown into water, crepitate beneath the finger, and, however carefully separated from the sound portion of the lung, yield upon pressure a reddish fluid intimately mixed with air. In the second stage the dark patches form nodules of a firmer and more compact consistence. Their cut surface is smooth, and when carefully detached from the surrounding parts, they crepitate none or but slightly, and sink rapidly when thrown into water. When the central portion alone of the nodule is subjected to pressure, a red sanious fluid escapes without any admixture of air. It is seldom that single lobules are found affected, the induration usually comprising four or five, forming a mass of the size of an almond. If the patient lives for some time, the intervening substance usually becomes affected, the lobular is converted into lobar pneumonia, and the inflammation runs its course, as in the ordinary cases of this latter form of the disease.

In the third stage of the disease, the section of the lung presents a greyish colour, inclining more or less to yellow in different cases. The pulmonary tissue is friable, and when pressed gives discharge to a purulent fluid, its texture being infiltrated with pus. Upon minute examination, some of the lobules will be found more projecting than others, their vesicles not being compressed, as in the less projecting parts.

According to Barthéz and Rilliet, there are two forms of lobular pneumonia. The first, which they denominate the *mammelonated*, is marked by nodules of hepatization, comprising one or more lobules, differing but little in colour and appearance from the surrounding tissue. Their limits are well defined, even when the neighbouring tissue is engorged. They are frequently surrounded by a layer, of about half a line in thickness, white, firm, and of a fibrous appearance. The hepatized portions slightly project above the surface of the incised lung, from the collapse of the surrounding air-cells. They vary in size from that of a hemp-seed to that of a pigeon's egg. They are of a spheroidal form, and have usually a regular surface. But a single nodule may exist in one lung, or there may be from twenty to thirty, or more. They are almost invariably surrounded by a circle of pulmonary tissue in a state of engorgement. The diseased portions generally attain the third stage of pneumonic hepatization, which terminates in the formation of an abscess.

In the same lung there may exist nodules of hepatization in the first and second stages, and also rounded masses of a straw colour, very humid when cut into. At a more advanced stage, the pus, which is at first deposited in the interstices of the pulmonary tissue, becomes collected in the centre of the nodules. This minute collection of pus is surrounded by two concentric zones, the internal one yellow—hepatization of the third degree;—the external one red—hepatization of the second degree. At a later period, the size of the abscess is increased at the expense of the inner zone, the outer zone at the same time passing into suppuration. At a still later period, an incision through the diseased portion of the lung reveals cavities varying in size from a few lines to four or five. These cavities are in general round, more rarely oval, and contain usually a thick tenacious yellow or greenish pus, perfectly free from any admixture of air. Sometimes small coagula of blood are mixed with the pus. These cavities are at first formed by a layer of hepatization, lined with a layer of concrete pus, or with a false membrane, yellow, soft, and easily detached. Subsequently, this membrane becomes changed into a thin, smooth, polished tissue, analogous to a serous membrane. The abscesses sometimes communicate freely with each other, and at the point where the bronchi penetrate their cavity, its mucous membrane presents a true solution of continuity. When the inflammation invades separately several neighbouring lobules, the cavity of the abscess is multilocular, each cell being isolated by a lamina of a hepatized tissue, upon the rupture of which the different abscesses communicate with each other. These abscesses have usually a tendency to approach the surface of the lung. An adhesion often takes place between the opposing surfaces of the pleura, or the pleura of the lungs becomes gradually thinned and finally perforated, giving rise to a true pneumo-thorax. It has happened, that an adhesion has formed between the lung and diaphragm, and the abscess of the lung has thus communicated with the peritoneal cavity. These abscesses are often completely isolated, and, with the exception of the thin layer of hepatization in their immediate vicinity, are surrounded with a perfectly healthy pulmonary tissue. Occasionally, however, they pervade the greater portion of the whole of one of the lobes. Their size is ordinarily in inverse proportion to their numbers. In the greater number of cases, they are confined to one lung, and are more frequent in the left than the right. They are met with most frequently in children under six years of age.

Partial, which is the second form of lobular pneumonia, is much less circumscribed than the preceding. Indistinct limits exist between the healthy and diseased portions, and the disease occupies a larger portion of the lungs. The diseased portions may throughout have reached the second stage, or at the centre alone, the circumference being still in the first stage; and this being in contact with several other portions of the lung, in a similarly diseased condition, nearly the whole of an entire lobe may present an admixture of the characteristics of pneumonia in the first and second stages, and when the disease has reached the third degree, it is strictly lobar.

In the major part of the cases, lobular pneumonia is double—the disease, however, being frequently much more extensive on one side than the other. A union of the three forms of pneumonia—mammelonated, partial, and general—is often met with in the same patient. The first is equally frequent in every portion of both lungs, while general pneumonia is far more frequent in the inferior lobes. Partial pneumonia is often disseminated throughout the three lobes—it is more frequent, however, in the inferior. Mammelonated pneumonia is of much more rare occurrence beyond the sixth year than partial pneumonia, while general pneumonia is still more rare than the former between the sixth and fifteenth years. (*See Barthez and Rillicet—Maladies des Enfants*, t. i., p. 61).

There are well sustained reasons for doubting the dependence of all the changes in the texture of the lungs, described as characteristic of lobular pneumonia upon inflammation of the substance of the lungs. Many of them are, unquestionably, produced by a collapsed condition of certain of the air-cells, occurring in the course of an attack of bronchitis. For the investigation of this subject, the reader is referred to the Editor's *Treatise on the Diseases of Children*, 4th edition.

The anatomical characters of lobar pneumonia in children are the same with those met with in the pneumonia of adults.

Inflammation of the bronchi, particularly of the smaller bronchial ramifications, pleurisy, and emphysema of the lungs, are common complications of pneumonia in children.

The lobular form of pneumonia is of the most frequent occurrence during childhood—it is also the most serious at that age.

Lobar pneumonia, occupying only one lung, when it occurs in children between six and fifteen years of age, whose health has not been impaired by previous disease, unless complicated by some secondary affection, is not a very fatal disease, if judiciously treated from its commencement. Its serious character is however greatly enhanced by its being complicated with other diseases. The most common of these are measles, whooping-cough, chronic enteritis, and small-pox.

Pneumonia in children is produced by the same general causes, as give rise to it in adults. It is common to both sexes, but more frequent in boys. It is particularly liable to occur in the same child after a shorter or longer interval.

In the treatment of the pneumonia of children, bleeding will very generally be demanded in the commencement of the attack. In young children leeches or cups should be applied to the anterior parietes of the chest, beneath the clavicles, or between the shoulders. Their number should be proportioned to the violence of the symptoms, and to the age and strength of the patient. In older children, however, bleeding from the arm should be preferred. The amount of blood drawn must be proportioned to the extent of the disease. The propriety of repeating the bleeding will depend upon circumstances. When the first bleeding has been well timed and carried to a sufficient extent, a second will seldom be required; whenever, however, the leading symptoms, particularly the dyspnoea, continue with little abatement, we should never hesitate to repeat the bleeding, either from the arm, or by leeches or cups, according to the violence of the remaining symptoms, the age of the patient, and the amount of strength remaining. It is, however, in the early period of the attack alone, that any very decided advantage is to be expected from blood-letting; in the more advanced stages of the disease, it will seldom be beneficial or admissible; though cases may occasionally occur, when the cautious application of leeches or cups to the chest or between the shoulders will be attended with marked relief, even after the disease has existed for several days.

In the commencement of the attack, if the bowels are torpid, it will be proper to administer a full dose of calomel, to be followed in a few hours, by a dose of castor oil, or in robust children, over three years of age, by a mixture of equal parts of magnesia and epsom salts. Subsequently the bowels should be kept regularly open by enemata, or occasional doses of some mild purgative; a grain of calomel, with half a grain each, of ipecacuanha and extract of hyosciamus, administered twice or thrice a day, will usually effect this object. Costiveness is not, however, very common in the pneumonia of infants; an opposite state of the bowels is a more frequent and troublesome symptom.

Subsequent to blood-letting, in robust children over three years of age, tartarized antimony, given in small doses during the day, will be found highly beneficial. But in younger children antimony in any form is a dangerous remedy, more particularly when there is any tendency to disease of the alimentary canal. Small doses of ipecacuanha and calomel will be found very generally to act beneficially in allaying the cough, dyspnoea, and general restlessness, and may be given to the youngest patient without any inconvenience resulting; adding to each dose a minute portion of powdered digitalis will in many cases be found advantageous. Occasionally the calomel will purge; should this be the case it will be necessary to add to it a grain or two of Dover's powder. After the violence of the disease has been considerably abated, we have found advantage from the administration, every three hours, of small doses of calomel, ipecacuanha and hyosciamus. Under the same circumstances the compound honey of squill may be given; in children over three years of age it is well adapted to allay the cough and dyspnoea: to the dose given in the evening a few drops of paregoric may be added.

Blisters to the chest are certainly very important remedies in the pneumonia of children. In violent cases, occurring in patients over five years of age, particularly when attended with much febrile excitement, they should not be applied until the violence of the symptoms have been abated by direct depletion; they should be kept on no longer than is necessary to produce a decided redness of the skin; they should be then removed and the reddened surface covered with a soft emollient poultice. In infants, as well as in slight cases, and in those occurring in children of a delicate

frame, or who are much debilitated, in place of a blister a thick slice of bread, dipped in vinegar and lightly sprinkled with powdered mustard, should be applied to the chest, and removed as soon as it has reddened the skin.

Warm sinapised pediluvia, or a sinapised hip-bath, will often produce a favourable revulsion from the lungs, and may be frequently repeated.

In stubborn cases Dr. West speaks highly of mercurial inunction; under its employment, he has seen recovery to take place even where the circumstances had seemed to warrant an unfavourable prognosis. The full value of mercurial inunction is seen in cases which have been neglected until the time for depletion has gone by, the patient having become exhausted, and the employment of calomel being forbid by the presence of diarrhœa. Dr. West directs one drachm of the mercurial ointment to be rubbed into the thighs and axilla every four hours, for children of four years of age. He has never seen salivation to be induced by it, but has observed the disease gradually to diminish in severity during its employment, and the solid lung to become once more permeable to air.

When in the advanced stage of the disease there is great exhaustion, with symptoms of impending suffocation, the use of carbonate of ammonia has been strongly recommended — but under such circumstances, there can be but little hope of the patient's recovery.

In chronic cases, our chief dependence is upon revulsives, applied either upon the chest, or upon the surface generally, and perhaps upon a judicious mercurial course, particularly by inunction.

In all cases of pneumonia, the exhibition of some mucilaginous drink, in small portions, and at short intervals, will be found to abate very sensibly the cough, and relieve the dryness of the fauces, which, in the early stage of the disease, is often a harassing symptom. A solution of gum acacia, or the mucilage of the elm bark, or pith of sassafras, sweetened, will be the best we can employ.

The diet of the patient, in the earlier period of the more acute cases, should be confined, almost exclusively, to these mucilaginous fluids — after the violence of the disease has been subdued, plain water gruel, arrow-root, or tapioca, may be allowed. When the disease occurs in young infants, they should be taken from the breast — the mother's milk being given to them in moderate quantities by means of a spoon, as well to prevent their stomachs from being overloaded, as to guard against the mischievous effects of the violent exertion of the respiratory organs in sucking.

The patient should be kept in a clean, well ventilated, and moderately warm apartment. It is all-important to guard him from cold and dampness, and from sudden transitions of temperature. He should be placed upon his bed or couch in a half-recumbent position, in order to render the respiration more easy, and to prevent the injurious consequences resulting from the stasis of fluids in the posterior portion of the lungs.

When the disease has arrived at an advanced stage, or involves a considerable extent of the lungs, the patient should be moved with the greatest care and gentleness, lest convulsions be induced.

After convalescence is fully established, gentle exercise in the open air, in mild, dry weather, may be taken; but, for a long period, the utmost care should be observed to guard against exposure to cold and dampness; and while a gradual improvement is made in the diet — if the child be weaned — all rich, stimulating, and indigestible food must be avoided, as well as the slightest excess in the use of those articles that are allowed. See *Condie on Diseases of Children*. — C.]

[TYPHOID PNEUMONIA. — A state of congestion or of inflammation, more or less intense, of the lungs, accompanied by that impairment of the sensorial powers, and morbid condition of the circulation and of the organism generally, which characterize the more grave forms of typhoid fever, has repeatedly prevailed in different portions of the United States, as an epidemic, often of wide extent, and, in its earlier visitations, producing an amount of mortality truly appalling.

The first notice we have of the appearance of this form of disease, remarks Dr. Dickson, (*Essays on Pathology and Therapeutics*, vol. i., 435), "was in the year 1806, in Medfield, a town of the State of Massachusetts, whence it spread gradually — extending itself, winter after winter, throughout New England, into Canada, and

the Middle States, progressing from village to village, and from one portion of the country to another, until, in 1813, it had reached Philadelphia. In the winter of 1815 it first prevailed in South Carolina, and was then, and more widely in 1816, epidemic; since which time its ravages in that State have been slight. It continues to show itself, sporadically, everywhere, I believe, where it has once found footing. In South Carolina we scarcely pass a winter without meeting with instances of it, especially among the blacks."

The disease is of frequent occurrence in other portions of the United States, and may be considered, to a certain extent, as endemic to several localities.

We are informed by Dr. Gibbes, (*American Journal of the Medical Sciences*, Oct., 1842,) that it prevails extensively during the winter months, on the rivers and swampy plantations, in the neighbourhood of Columbia, South Carolina, and destroys more negroes than all the other maladies combined to which they are ordinarily liable.

According to Dr. Dickson, it has not been observed farther south than the State of Georgia, nor is it of very frequent occurrence beyond the latitude of Charleston.

Typhoid pneumonia, as it prevails in the United States, is very similar in character to, and is probably the same affection as that described by Sydenham, Huxham, and others of the older writers, as peripneumonia notha. Sauvages has very accurately portrayed the disease under the denomination of peripneumonia typhoides. An account is given by the late Dr. John Bard, of New York, of an epidemic that prevailed on Long Island, in the winter of 1749, which he terms a malignant pleurisy, that in all its essential features corresponds exactly with the disease under consideration; a similar affection is also noticed by Dr. Hugh Williamson, as having prevailed in North Carolina in 1792.

Typhoid pneumonia is described by Dr. Stokes as not uncommon in Ireland, while Dr. Burne, of the Westminster Hospital, mentions that a great number of cases of what he calls "the spotted fever," were brought into that institution in the year 1838. He describes the affection as "an adynamic or typhus fever, combined with a latent and dangerous pneumonia, and exhibiting on the surface a very regular and uniform spotted eruption — not petechiæ." This is evidently the same disease as the typhoid pneumonia of this country, which, when it first attracted attention, was so frequently attended with an eruption upon the skin, that it was very generally designated by the popular name of spotted fever. The eruption, however, soon ceased to attract attention; it was seldom observed as a phenomenon of the disease south of the Potomac, and even in the northern and middle portions of the United States, the eruption ceased early to present itself.

Dr. Macintosh, of Edinburgh, describes a form of pneumonic inflammation, attended by symptoms that are generally denominated typhoid, and which, in consequence, has obtained the name of pneumonia typhoides, as very prevalent among the British troops stationed in exposed situations along the coast, and in large garrisons where the duty is severe. Dr. Mackintosh, however, objects to the adjunct typhoides, as expressing erroneous ideas of the pathological condition of the system; — and the objection is not without foundation — for although that peculiar form of pulmonary engorgement quickly followed by inflammation and hepatization, to which the term typhoid pneumonia has been applied, does very frequently occur in connection with genuine typhoid fever, it is likewise a very common complication in certain seasons and localities of the bilious remittent fever, while it is also met with in cases of gastro-enteritis, of ambulant and erratic erysipelas, of diffuse cellular inflammation, and of other diseases, and by which the thoracic affection is more or less modified, and often completely masked; hence to denominate the pneumonic disease as essentially and invariably typhoid in its character is evidently a misnomer, and very liable to lead to serious errors in practice.

In the United States the disease is known by various names, according to the predominance of particular symptoms. In the more violent cases, the patient being suddenly seized with a very severe chill, accompanied with marked coldness of the surface, it is, according to Dr. Gibbes, frequently denominated the *cold plague*. The head being almost invariably affected, before the pneumonic symptoms are developed, it is often called *head pleurisy*. In the autumn or spring, when, in particular districts of country, it is frequently attended by the symptoms of ordinary bilious fever, it is called *bilious pleurisy*. From the symptoms of prostration by which the disease is

so generally attended throughout its whole course, and the rapidity with which the patients sink in the more violent cases, the term *typhoid pneumonia* has become, however, the one by which it is most frequently designated.

In its mode of attack, and the general symptoms by which typhoid pneumonia is ordinarily attended, there is no uniformity. Usually, however, the disease is ushered in by a chill, which is often of great severity and long continuance,—the heat of the whole surface being to the touch much below the standard of health. The cold stage is not unfrequently so intense as to destroy the patient before the slightest reaction occurs. Where the disease is violent in its attack, the patient may suddenly become cold and pulseless, lethargic, and often insensible without previous complaint. Dr. Gibbes has known instances in which the patient was found dead, or died within three or four hours after being in a condition of apparent health.

During the cold stage, the respiration is short and oppressed, and a pain on one or other side of the chest is generally complained of; pain of the head is also present in most cases; and not unfrequently the patients experience severe pains in the back, limbs, and other parts of the body—similar, occasionally, to those of rheumatism. The muscular strength is greatly prostrated, and there is a sense of general uneasiness and great restlessness. After a period, longer or shorter in different cases, but usually protracted, reaction ensues, and the heat of the surface is restored—it is seldom, however, increased much above the ordinary standard of health. The heat is often unequally diffused over the surface—portions being decidedly hot, while others are comparatively cool. Occasionally, the skin becomes hot, dry, and harsh, while, at other times, it is relaxed, cool, and clammy. The pulse, when reaction ensues, becomes somewhat fuller, and more quick and frequent, but in very few cases does it acquire any degree of tension, excepting, perhaps, when the disease attacks young subjects and those who retain some degree of vigour. Most commonly the pulse is soft, or it yields to the slightest pressure. During the febrile stage, the pain, oppression of the chest, and difficulty of respiration are increased, and, very generally, a cough comes on within the first twenty-four hours, by which the pain in the thorax is greatly aggravated. When the cough is attended with expectoration, the pain in the side is considerably relieved, and the oppression of respiration diminished. When, however, the cough continues dry, or the expectoration is slight, all the more serious symptoms become aggravated. The matter expectorated is a thick, tenacious mucus, often tinged with blood, but at other times of an ash or dark-brown colour. The respiration, besides being oppressed, is usually hurried and irregular—the patient's spirits are greatly depressed—he often utters deep and heavy sighs, and complains of a sense of weight, or of constriction at the præcordia; he is often affected with nausea, and occasionally with vomiting.

Dr. Mann (*Med. Sketches*, page 308), notices, as a common symptom of the disease, a remarkable pink-coloured suffusion over the whole face, distinct from the usual febrile redness of the cheeks—the face becoming, at the same time, puffed or bloated. This appearance is most conspicuous in individuals of a light complexion; it is present, also, upon the body, but to a less extent. In many cases it is not observed even on the face, or in a very slight degree, and for a short period.

The tongue, in the first period of the disease, is often clean but red, particularly at its edges; in other cases, and perhaps most commonly, it is thickly coated with a yellowish mucus, which, in the progress of the disease, changes to a dark-brown—the tongue becoming, at the same time, dry, hard, and rough—often chapped. Upon the separation of the crust, the tongue presents, not unfrequently, a bright-red colour, which colour occasionally pervades also the fauces.

In many cases, the patient exhibits from the very commencement of the attack, particularly where there is much pain of the head, more or less delirium, and great restlessness.

As the disease advances, the teeth and the whole interior of the mouth become coated with a dark-coloured sordes; the breathing becomes shorter and more oppressed—the strength more prostrated, the pulse smaller and weaker—the patient sinks into a state of low muttering delirium or of coma, more or less complete, and the fatal event takes place as in the ordinary cases of typhoid fever.

The duration of the disease is very variable. Death, as we have seen, may occur within a very few hours from the commencement of the attack. Dr. Mackintosh has

seen the disease, in the strongest subjects, run its course to a fatal termination in from forty-eight to sixty hours; while Dr. Gibbes has known patients to be destroyed by it in from three to twenty hours. In other cases, the disease may continue for several days before a fatal event occurs.

In cases where, under an appropriate treatment early commenced with, the nervous power is quickly aroused, the activity of the circulation is excited and a free action of the peripheral capillaries restored, the attack has been known to be cut short, without the occurrence of any symptoms of pneumonic disease.

When symptoms of pneumonia become developed, these will often yield to a proper treatment, within the first thirty-six or forty-eight hours, though they will occasionally continue for six or seven days, or even longer. The pulse increasing in volume and in firmness, the surface becoming, throughout, warm, soft, and moist, the tongue cleaner and less red, the delirium diminishing, the expectoration becoming more free and copious, the cough less frequent and annoying, the pain of the thorax less intense, the respiration more full and easy, and the occurrence of a quiet sleep, from which the patient awakes refreshed and with greater cheerfulness, are the certain indications of amendment — recovery, however, is in general very slow — the period of convalescence being protracted, while relapses readily occur from slight exposure or the least imprudence of any kind.

Dr. Gibbes states, that he has frequently known patients who were convalescent and able to walk about, complaining, in fact, of nothing but debility, to “yield suddenly to a cold change of weather, and die in a few hours, or linger several days with pneumonic symptoms.” Symptoms that were before mild and favourable, will often become aggravated upon a change in the atmosphere to cold and damp. If a patient has been much enfeebled by a first attack, a second is very likely to prove fatal.

In many cases of pneumonia typhoides, instead of a gradual decline of the symptoms of thoracic disease taking place, these cease suddenly, and a severe pain is immediately experienced in some other and perhaps remote part of the body, as in the region of the liver, in the bowels, or in the head, attended with the other symptoms of inflammation in these parts. According to Dr. Gibbes, when upon the cessation of the thoracic symptoms, a hemorrhage from the bowels ensues, it is generally critical — when, however, inflammation of the brain or peritoneum takes place, the case usually terminates fatally.

The foregoing is the description of pneumonia typhoides as it most frequently presents itself. In the different epidemical visitations of the disease, at different seasons, and in different localities, or even during the same periods and in the same places, it not unfrequently, however, assumes a very different form. Thus, in some cases, the only symptoms which the patient exhibits are extreme prostration and wandering pains of the back, loins, shoulders or legs. In other cases, after a severe and protracted chill, the patient is seized with severe pain of the head and back, and great gastric distress—delirium soon sets in, which quickly gives place to coma, and death ensues within a few hours.

“Occasionally,” remarks Dr. Gibbes, “an acute pain in the back part of the eye, in the ears, or side of the neck, with stiffness of the muscles, is present. In severe cases the tonsils, the submaxillary and sublingual glands are swollen, with acute pain in swallowing; these are usually the worst cases.” In a few instances the symptoms of genuine erysipelas present themselves on some portion of the skin, and invade successively almost every part of it.

In these irregular forms of the disease, the symptoms of the thoracic affection are often very slight, or they may be entirely absent. There is usually, however, some sense of tightness about the chest, some difficulty of respiration, and a slight occasional cough—with or without expectoration; and it is remarked by Dr. Stokes, that the physical signs of pneumonia may frequently be detected in cases unattended with dyspnoea, pain, cough, or expectoration.

A very common form of the disease under consideration — and which at certain seasons, and in particular districts, is even more prevalent than that to which the appellation typhoid is ordinarily applied—is the one usually known as bilious pleurisy or bilious pneumonia.

In this, the attack commences with symptoms differing but little from those which usually usher in an ordinary case of bilious remittent fever—there is, perhaps, in

general, a more severe and protracted chill, and a sense of distress and oppression about the chest, which is not usually observed in the latter disease. Occasionally, the attack is preceded, for a day or two, by a sense of fulness and weight in the right hypochondrium, and, in a few cases, by symptoms of a dysenteric character. Very generally there is severe pain of the back and extremities, and often of the head also. Almost invariably, the attack is accompanied by an acute pain of the forehead—well-marked febrile symptoms, with, usually, decided exacerbations in the morning and remissions towards evening.—During the exacerbations the face is flushed, and as the skin, from the commencement of the disease is more or less tinged with bile, the mixture of red and yellow gives to the countenance a very peculiar, sickly aspect. The eyes are red and watery, the conjunctiva having often a deep yellow hue. In many instances, it is only after the fever has continued for several days that pain in the chest is complained of: this is sometimes very severe and acute, more commonly, however, it is obtuse—of an aching rather than of a lancinating character—there is, at the same time, a sense of weight and oppression of the chest, with more or less difficulty of respiration and cough. The cough is at first dry, and its repeated paroxysms cause an increase of the pain in the thorax and head. The expectorated matter is frothy and of a yellowish colour, often streaked with blood, and of variable consistence. The tongue is, at first, coated on its sides with a whitish mucus, while at the centre it is covered by a dark-yellow or brownish crust—the edges of the tongue are ordinarily of a decided red. As the disease advances, the tongue becomes dark-brown, dry, and hard. The pulse is usually small, frequent, and quick, with a slight degree of tension.

There is always more or less gastric distress, and very commonly vomiting, the matter discharged from the stomach being often bile or a thick ropy mucus mixed with bile. In many cases the epigastrium is hot, and painful upon the slightest pressure. The urine is always of a deep yellow colour from the presence in it of the colouring matter of the bile.

The stage of excitement in bilious pneumonia is ordinarily of short duration, and, unless the disease is arrested by an appropriate treatment, great muscular prostration speedily supervenes, and the same train of symptoms ensue as in the typhoid form of the disease.

In the affection we have described, under whatever form it may present itself, the period of convalescence is always slow, irregular, and for a long while imperfect. "Chronic hepatization, with or without hectic fever, or a lurking congestion, may continue for weeks; and although, under appropriate management, the disease may be ultimately removed, atrophy of the lungs, with or without ulcerative disease, is often established. In certain cases, months may elapse before the respiratory murmur is heard, and, in many instances, it is never re-established. On the other hand, it has been known to cease in a single day, on the supervention of an attack of gastritis or enteritis." (*Dunghison's Practice of Medicine*.)

The principle exciting cause of pneumonia typhoides is unquestionably protracted exposure to a damp and cold atmosphere, while the predisposition to its attacks is promoted by all those causes which tend to reduce the vital energies of the system—as bodily or mental fatigue, intemperance, improper or deficient diet, insufficient clothing, mental distress or anxiety, long watching, previous disease, &c. Nothing, remarks Dr. Mann, predisposes to its attack in so high a degree as an intemperate use of intoxicating drinks. The soldiers, says Dr. Mackintosh, were often seized with the disease who were exposed at night as sentinels—"instead of walking about they frequently stand shivering in their sentry-boxes, the surface continues long chilled, and with a view to fortify themselves, and to produce warmth, they are in the habit of drinking ardent spirits in considerable quantity."

It is a common complaint among the poor and labouring classes in many parts of this country, during the prevalence of long-continued cold and damp weather, such as frequently occurs during the spring and autumn, in the more northern states, as well as during the open winter of the middle states. In the south, according to Dr. Gibbes, it is rarely met with on highland plantations, and if at all, is confined to such negroes as are more or less exposed to work on low or wet ground. On the swamp plantations the disease is endemic.

As we have already stated, the disease occasionally occurs as an epidemic, but

generally, during seasons when the temperature of those districts in which it prevails is marked by sudden and considerable vicissitudes from heat to cold, and by extreme and long-continued moisture.

Typhoid pneumonia more frequently attacks males than females, and adults than children — this is a statement in which nearly all who have written upon the disease concur. The predisposition of adult males to its attacks, is very readily explained by the amount of exposure and fatigue to which they are usually subjected being much greater than that of females and children—and probably, also, from the fact that their habits, generally speaking, are much less temperate. The disease is not, however, confined to any age, nor are females and children entirely exempt from it, particularly when it prevails as an epidemic. It is usually, however, most severe in individuals over fifty years of age, and is very seldom seen in children under ten years. The negro race is particularly liable to its attacks.

In the treatment of pneumonia typhoides much must necessarily be left to the judgment of the practitioner. In the selection of his remedies, more perhaps than in any other disease, must be guided by the particular character of the symptoms present in each case. It is all important that the true nature of the disease be carefully investigated in its earliest stages—it being then, in its ordinary form, readily controlled by an appropriate treatment, and, even when marked at its onset by symptoms of very considerable severity, it may often be arrested by prompt and judicious management.

In this disease, Dr. Gibbes remarks, and a similar observation is made by others, “if the cases are immediately attended to, it is found quite manageable, as much so as an ordinary catarrh; but when neglected for twelve or twenty-four hours, and the symptoms are at all aggravated, the patients are very apt to die.”

We shall often succeed, when the patient is seen during the first period of the attack, or during the cold stage, as it is not improperly termed, in rousing the nervous energy—producing a free and equable circulation, and a due degree of heat and moisture upon the surface, by resorting at once to moderate doses of opium, camphor, calomel, and ipecacuanha, in conjunction with the milder class of diffusible stimulants internally, and the application of heat and rubefacients externally. By this treatment, early and judiciously pursued, and carefully watched so as to prevent a state of over-excitement being produced by it, the engorgement of the lungs may often be prevented or removed, and a speedy restoration of health secured to the patient.

In the more open form of the disease, known as bilious pneumonia, the early administration of an emetic will often be found beneficial. Richter states, that in this form of the disease, emetics will often remove the pain and affection of the chest as by a charm, and Stoll makes the same observation (*Ratio Meden.*, i.). Dr. Eberle states, that in the few cases of bilious pneumonia he had seen, the utility of emetics in its treatment was strikingly evinced. They, in general, bring on an uniform diaphoresis, promote expectoration, and allay the pain in the thorax, often almost immediately. Dr. Dickson also has been much pleased with the effects of the early administration of an emetic, or an emetico-cathartic. A combination of ipecacuanha and calomel may be given, or the sulphate of magnesia dissolved in a strong infusion of seneka or serpentaria, with the addition of twenty grains of ipecacuanha. Dr. Mann, likewise, speaks favourably of the effects of an emetic of ipecacuanha. In the more decidedly inflammatory cases, the emetic was not administered by him until after bleeding and cathartics had been employed; especially where the head or chest was affected with severe pain. When, after the occurrence of expectoration, this had become arrested from any cause, small emetics, he states, were found beneficial, and in many cases had to be frequently repeated. The emetico-cathartic or even the emetic alone, is, however, a remedy of very doubtful propriety in cases attended with early symptoms of prostration and extreme muscular debility.

The propriety of blood-letting in any of the forms of typhoid pneumonia, has excited not a little controversy. By some practitioners, the use of the lancet is condemned in every case, as a remedy fraught with danger, from its liability to induce speedily a state of prostration from which the patient is with difficulty roused; while others of equal authority insist upon the necessity of full and even repeated venesection — considering it to be an important, if not an indispensable remedy in the treat-

ment of the form of pneumonia under consideration. This discrepancy of opinion is satisfactorily accounted for by the very different characters under which the disease presents itself in different localities, and at different periods—often, indeed, during the same epidemic visitation. South of the Potomac, we are informed by Professor Potter, that the disease is seldom so inflammatory as along the shores of New Jersey, Delaware, and Maryland; and the farther south, the more it is said to assume a decided typhoid complexion. In the winter epidemic of 1815–16, along the northern frontier of the United States, we are assured by Dr. Mann, that in many districts “the disease was highly inflammatory from its commencement to its final resolution,” and that, “it was as idle to administer stimulants for its cure, as it would have been to have poured oil on fire to extinguish the flame.” “Its cure,” he adds, “depended upon the assiduous administration of the antiphlogistic regimen: evacuants, expectorants, and diaphoretics, with the aid of blisters.”

It is very certain that in the ordinary cases of typhoid pneumonia, the use of the lancet will seldom be demanded, and in many, would be altogether inadmissible. Cases, it is true, will not unfrequently occur, in which the detraction of a moderate quantity of blood from the arm, during the early period of the febrile stage, will be productive of the best effects. General blood-letting, however, should always be resorted to with the utmost caution—perhaps it would be better, in every instance where symptoms of a typhoid character early set in, and the loss of blood is considered advisable, to apply cups to the chest in preference to resorting to the lancet. In cases of bilious pneumonia, blood-letting will be much more frequently demanded than in the typhoid form of the disease; but even in these it should be resorted to only in the early period of the attack, and it is more safe to take away a sufficient amount at the first bleeding, than to trust to small and repeated bleedings. In this form of the disease, when much pain or tenderness of the epigastrium is present, leeches or cups to this part are always proper, and will often be found to afford very decided relief.

The bowels should be early evacuated by some mild but effective laxative—the best is unquestionably calomel in moderate doses, followed by castor oil or magnesia. Active or watery purging should always be cautiously avoided.

In the cases marked by early prostration, and extreme muscular debility, we should resort at once to moderately stimulating diaphoretics; of these, according to Dr. Dickson, camphor, nitrous ether, the carbonate and acetate of ammonia are the best; and they are rendered more beneficial by combining them with Dover's powder. “The efficacy of all these,” he adds, “will be much aided by the pediluvium, and by the application of warm fomentations, poultices, and heat in various forms to the surface of the patient. Cataplasms with mustard must be laid over the chest, if pain or dyspnoea is present, and applied also to the wrists and insteps. Epispastics are also of use, by their double power as stimulants and revulsives; the back of the neck, if the head be affected, the sternum and the epigastric region, if the lungs or heart or stomach suffer, should be selected for their application. There has been some dispute as to the preference due to the dry or moist form of heat, as the best to be resorted to in this disease. It is, I think, easy to decide. If the skin be dry, I prefer fomentations, or even the vapour-bath; if moist, I prefer bottles of hot water, heated bricks, bags of hot salt, chaff, &c. Sweating will, in the greater number of cases, come on readily, but must be regulated. If too profuse, and kept up for too long a time, it may prove injurious and debilitating. You restrain it by substituting dry for moist applications, and removing some of the bed-clothes, and changing cautiously the body linen of the patient; dry garments carefully and well aired, being put on in the place of those moistened by the cutaneous discharge.”

In cases where a tendency to sinking is early evinced, Dr. Gibbs recommends small doses of calomel as a general excitant of the secretions, with camphor, opium, carbonate of ammonia, and free vesication.

In nearly every form of the disease, whether typhoid, bilious, or more openly inflammatory, the effects of small doses of calomel, combined with ipecacuanha and opium are spoken of as particularly beneficial. Large blisters over the chest will also, in most cases, be found of the highest importance, from the very commencement of the attack. In obstinate cases, Dr. Mann directs them to be renewed daily until the pain of the chest is removed.

Where the patient's strength rapidly fails, and he is sinking into that low typhoid condition which marks the second period of the disease, stimulants must be freely resorted to: of these Dr. Dickson prefers "the volatile alkali in large doses, from five to ten grains every half hour or hour, with wine whey or brandy toddy; spts. nit. dulc., spts. of turpentine, the tincture of cantharides." "I can set," he remarks, "no limit to the administration of this class of remedies, but the excitement of a notable degree of reaction, which being observed, will guide you in the future quantities to be exhibited; taking care, however, that the patient shall not suffer by their timid or inefficient amount, nor be allowed to retrograde by any sudden subtraction of dose."

"It is well to be reminded," observes the same writer, "that in this strange disease it is never permitted to despair of your patient, recoveries being in considerable number recorded, from circumstances the most deplorable, and, indeed, to all reasonable anticipations, absolutely hopeless."

During the whole period of convalescence the patient will require to be watched with care. — "You must abstract gradually from the amount of stimulants which have been given him, and substitute in their stead the more permanent tonics." Of these each practitioner has his favourite. Arsenic is preferred by many of the New England physicians, and is, according to Dr. Dickson, without doubt, highly serviceable. The muriate of iron is also spoken of as well adapted to this period of the disease — and is certainly preferable in all respects to the arsenic. Dr. Mann states, that the only stimulant employed by him in the convalescent state, was a mixture of spts. nit. dulc., and aqua ammoniæ; a teaspoonful of this proved a cordial and expectorant, at the termination of the disease, when repeated every two or three hours; as did, also, a mixture of equal parts of the camphorated tincture of opium and antimonial wine, where the cough was troublesome. Other practitioners prefer, as a tonic, at the close of the disease, and during the period of convalescence, the cinchona or the sulphate or muriate of quinia. Dr. Dickson gives the bark in infusion, combining it with serpentaria, adding to each dose a small proportion of carbonate of potass, and camphorated tincture of opium. The patient should be supplied with a light diet of nourishing and easily digested food — and should be guarded sedulously from the slightest amount of exposure to cold or damp, and should be guarded from sudden alternations of temperature for a considerable time after recovery—he should to that end wear flannel next his skin, and adapt his clothing not only to the season, but to the temperature of each day and each portion of the day. — C.]

In the next lecture I shall speak of pleurisy.

LECTURE LII.

Pleurisy. Its anatomical characters; false membranes; liquid effusion; effects of these upon the shape and contents of the chest, and upon its healthy sounds. Symptoms of Pleurisy.

I PROCEED this afternoon to the subject of *pleurisy*; having in the last lecture concluded what I had to say on that of pneumonia: that is, I pass from inflammation of the *substance* of the lung, to inflammation of its *investing membrane*. The two frequently exist together: but when that is the case, the one, in general, predominates greatly over the other. Pleurisy, however, without pneumonia, is much more common than pneumonia without pleurisy. When both are present, but the pneumonia forms the main disease, the term *pleuro-pneumonia* is applied to the compound malady. The whole interest of such a case merges in the pneumonic inflammation. Again, when both are present, but the pleurisy predominates, the compound affection is sometimes called *pneumo-pleuritis*.

The pleura, as you know, is one of the serous membranes. Its inflammation is attended therefore with those *events* which I formerly took some pains to describe as belonging especially to that particular tissue. The inflammation is of the adhesive kind: it is accompanied by pain; by the pouring out of serum, of coagulable lymph, of pus, or of blood. I think it will be best, in this instance also, to lay before you some account of the morbid anatomy of the disease, before I consider its symptoms.

The alterations that take place in the inflamed membrane itself are not very striking or important. Experiments upon living animals, made by introducing some foreign substance, or injecting some slightly irritating liquid, into the cavity of the pleura, have proved that, as in other cases, inflammation is attended with *redness* of the part affected. But it is scarcely ever that we observe this effect *alone* of inflammation, in the pleura of a dead person; unless, indeed, he has died of some other complaint while he happened to have *incipient* pleurisy. The pleura has been said to be thickened by inflammation; but that I apprehend to be a mistake. It often *appears* to be thickened, in consequence of the superposition of a false membrane — a layer, or several layers, of plastic lymph. But actual thickening of the pleura itself seldom or never happens. Neither does the pleura easily soften, or readily ulcerate, under inflammation. It peels off, in some cases, from the lung, or from the ribs, with more facility than in the sound state.

The most remarkable effects of pleurisy result from the effusion of coagulable lymph, or of serous liquid, or of both, into a shut sac, having peculiar anatomical relations. One part of the membrane lines the firm walls of the chest: the other part envelopes the soft and compressible lung. The opposed surfaces of this closed and empty bag being *apposed* also, but freely moveable one upon the other, very different, and even contrary, effects may be produced by its inflammation. The pulmonary pleura may be glued to the costal pleura, so as to prevent all lateral movement between them, and to obliterate the pleural cavity: or the two surfaces of the membrane which are naturally in contact, may be forced unnaturally apart by a pouring forth of serum between them; or the opposite surfaces of the pleuræ may be united by coagulable lymph in some places, and separated by effused fluid in others. And great differences will arise in the symptoms, and in the gravity and tendency of the complaint, according as one or another of these different conditions of the contents of the thorax is established.

Let us first consider the effect of the throwing out of coagulable lymph only; or, of what comes to the same thing, the effusion of coagulable lymph with a certain quantity of serum, which last is soon reabsorbed.

One consequence of this is the formation of *false membranes*. These, indeed, are formed whether there be much or little serum poured out. We continually meet with them, sometimes when we least expect to do so, in the dead body. They vary

FIG. 55.

FIG. 56.

Fig. 55. — The lymph of pleuritis, with new vessels already formed in it; a deposit of fat has also taken place. Magn. 20 di.

Fig. 56. — Straw-colored lymph, coating the lower lobe of an inflamed lung, in recent pleurisy, before there was a trace of adhesion to the costal pleura. The outline represents one of two coils of new vessels, seen under the microscope in the fringe of lymph at the lower end.

greatly, in different cases, in respect of their thickness, situation, extent, organization, and effects.

When the lymph is first deposited upon the free surface of the inflamed pleura, it is soft, and of a greyish white colour, like paste somewhat. It soon, however, acquires an increase of consistence, and shows marks of vitality; becomes, in short, organized. Red points begin to appear in it, few in number and widely separated at first; but they presently multiply, and lengthen into reddish streaks, which run along the surface of the effused matter. Soon these red streaks may be perceived to be slender vascular canals; and at length they inosculate with the vessels of the pleura, and the lymph, converted into a false membrane, becomes a constituent part of the living frame.

It is curious, and useful too, to know how rapidly this work of organization may go on.

Andral made experiments upon the pleuræ of rabbits, by injecting acetic acid into them. He sometimes found, at the end of nineteen hours, soft and thin false membranes, traversed by numerous anastomosing red lines. In other rabbits, placed under circumstances which appeared to be exactly similar, no such result had taken place at the end of a much longer period; but the pleura contained only a serous or puriform liquid, mixed with unorganized flakes of lymph. Now similar differences have been remarked in the human subject, under disease. False membranes, already vascular, have been found in the bodies of persons who died of pleurisy after a very few days' illness: while in other patients, who had lived for many months after the invasion of the disease, there has been no trace of such vascular membranes. It is clear, therefore, that the organization of the lymph does not depend solely upon the length of time that has elapsed from the period at which it was poured forth. It has much more to do with the previous state and habit of the patient. *Ceteris paribus*, plastic lymph and early adhesion are more to be expected in young, strong, and healthy persons; curdy unorganized lymph, granular deposits, with copious and abiding serous effusion tending to become puriform, in such as are old, feeble, cachectic, and scrofulous.

The extent of these false membranes varies, according to the extent of the inflammation which has produced them. When that has been general, they cover the whole lung, and line the whole costal surface, and spread themselves over the diaphragm and mediastinum of the same side. Supposing that there is no serous liquid effused, or that it is absorbed, the lung then becomes everywhere adherent to the sides of the cavity which contains it. The medium of adhesion, which is soft and tender while it is recent, grows firm, and assumes the characters of areolar tissue, when the union is of old standing.

The thickness of the false membranes is also extremely variable. Sometimes it is not more than that of the pleura itself, and the lymph might then, in the absence of adhesion, be almost overlooked. But in the majority of cases their thickness is much greater than this. Frequently several distinct layers or strata are seen, superposed one upon another, to a considerable depth.

Are there any auscultatory signs of this process of adhesion, when it occurs? Yes. There is a morbid sound, not hitherto mentioned by me, whereby it is sometimes disclosed: the sound, namely, of *friction*; the sound produced by the rubbing together of the dry, or inflamed and roughened surfaces. You doubtless are aware that every time a tolerably deep inspiration takes place, the relation between the ribs and the lung undergoes a change. While the ribs are elevated, the lung descends a little: and consequently any given point of the surface of the lung is no longer in contact with the same point as before of the thoracic parietes. You may convince yourselves of this fact by carefully making a small incision through an intercostal space, in a living animal. Now the pulmonary pleura, when that membrane is inflamed, does not slip and glide over the costal pleura in its usual smooth and noiseless manner; but it makes a creaking or rubbing sound, which the ear, applied to the corresponding surface of the chest, readily catches. I have very many times heard this; yet it is not at all a familiar sound: indeed I had heard it, in one instance, some time before I knew what the noise meant. The sound has, mostly, an interrupted character, occurring in a series of three or four jerks. The patient is often made aware of the harsh movement, by some internal sensation; and a bystander, who places his hand flat upon the corresponding part of the thorax, may sometimes feel this grating of the

membrane upon itself. You may wonder, as adhesions are so common, that this sound, and these sensations, are not oftener heard, and felt. In truth, they are transitory phenomena, and cease, of necessity, as soon as adhesion prevents any further motion of the opposed pleuræ upon each other. If we do not happen to listen during that period, usually a short one, in which the pleuræ, roughened by inflammation and effused lymph, but not separated by liquid, still chafe against each other, we lose the opportunity of hearing the sound at all. This *rubbing* sound, this noise of *friction*, we shall find to be of greater importance in relation to certain diseases of the heart, than in cases of acute pleurisy. In pleurisy the *liquid* matters poured into the membranous sac have far more interesting consequences: and to these I now beg your attention.

In some instances we find, after death, a clear, serous, or watery fluid, without colour, or of a pale lemon-colour, and perfectly limpid and transparent. This may occur, independently of inflammation of the pleura; from some mechanical obstacle to the circulation. It then constitutes a species of dropsy; a true *hydrothorax*: and this, though less common than ascites, is by no means an *uncommon* consequence of disease of the heart. When the effusion does not proceed from a cause of that kind, it is always, probably, the result of inflammation of the pleura itself, although we may find only a slight degree of redness upon its surface, or a few patches of coagulable lymph. More frequently, besides this clear liquid, with flakes of albuminous matter floating in it, there is also a coating of lymph on the inflamed membrane. Very often the thinner fluid is turbid, or whitish, like whey; sometimes it is distinctly puriform; sometimes it is tinged more or less deeply with blood; sometimes it consists of nothing else but blood, which has separated into serum and crassamentum. There being no wound, nor visible rupture, of large or of smaller vessels, we conclude, in such cases, that the blood has exuded from the membrane by what I have previously spoken of as capillary hæmorrhage.

The different kinds of fluid effused into the pleuræ are always, or almost always, without smell; — provided that it has remained a closed bag: I mean when no communication has been established between the cavity of the pleura and the external air, either through an opening in the walls of the chest, or through a pulmonary fistula leading to the trachea, or through some breach in the œsophagus. I have met with but one exception, and that a doubtful one, to this rule. A patient died in the hospital, who, some years before, had nearly killed himself by swallowing, in mistake for beer, a solution of caustic potass. The result of this had been ulceration, and subsequently stricture, of the gullet. His left pleura was perfectly full of most stinking pus; and we were unable to detect any channel of communication with the outward air, although the circumstances of the case rendered it not improbable that such a channel might have existed.

Sometimes air, or gas, is found in the cavity of the inflamed pleura; either alone, or (what is much more common) together with a liquid. We ascertain this fact, in the dead body, by the hissing sound that takes place as soon as a penetrating incision is made between the ribs: or by opening the thorax under water, and noticing the escape of air in the form of bubbles. It is probable that these gases are sometimes secreted or exhaled from the diseased membrane; sometimes they are the product of decomposition within the cavity; but, for the most part, they are admitted from without, the sac of the pleura communicating somehow with the external air.

Such being the fluid matters that frequently occupy the cavity of the pleura when that membrane has undergone inflammation, let us next examine the necessary effects of their being collected in that part. These effects will obviously vary considerably according to the quantity of the fluid that accumulates.

Now the quantity of fluid may vary from less than an ounce to several pints. At first it is lodged in the cavity of the pleura solely at the expense of the yielding lung, which is compressed to make room for it. But if the quantity continue to augment, other parts are at length displaced by the increasing pressure, the boundaries of the chest on that side are stretched, and even the abdominal viscera are thrust out of their natural position. The lung is pushed back towards the mediastinum and vertebral column, and flattened and brought to lie in the smallest possible compass; the diaphragm is forced downwards, which sometimes gives rise to a considerable prominence of one or the other hypochondrium, the spleen and stomach

being displaced on the left side, or the liver on the right. The ribs are separated too; the intercostal spaces become wider, and are pushed out to the level of the bones, and the whole of the affected side is smooth and obviously larger than the other. The mediastinum also undergoes some change of position, being driven more or less towards the side opposite to that on which the effusion exists. If the liquid happen to fill and distend the left side of the thorax, the heart may be moved out of its natural place, and be heard, and felt, and seen to beat on the right of the sternum. Andral mentions having met with only one instance of that kind. I suppose that I cannot have witnessed less than a score such. So again the heart may be carried beyond its proper place, to the left, by a large effusion into the right pleural cavity.

FIG. 57.
Portion of the lower lobe of the left lung of a patient, compressed by turbid serum, occupying the pleural cavity. A thick layer of lymph covered the hepatized portion of lung: it was perfectly smooth from the contact with the liquid, and there was a free scalloped margin at some parts, of an inch in breadth. The exudation-matter consisted of filamentous matter, entangling corpuscular fibrin.

I say when the liquid is accumulated in very considerable quantity, the lung is pressed into the form of a thin cake, which occupies a very small space alongside the vertebral column: and if it happen to be covered over and concealed, as it often is, by a strong layer of adventitious membrane, we might fancy, at first examination, that it had completely disappeared. It was in cases of this kind — especially when the effused fluid consisted of pus — that the lung was erroneously represented by the older observers as having been *destroyed* by suppuration. However, you will always find the lung there if you take the pains to look for it, and to divide the false membranes that bind it down: and, in many instances, it is sound also. Its surface may indeed, be wrinkled, but the lung itself is capable of being restored to nearly its former volume by insufflation, as it is called; by blowing air into it through the principal bronchus of that side. In this compressed state the lung does not crepitate under the finger: it is dense, and sinks in water; in fact it is wholly void of air, and has been brought, by the pressure of the fluid around and upon it, into nearly the condition of the fœtus that has never breathed. But its firmness, its resistance to being torn, and its capability of being again inflated, prevent our confounding it with hepatized lung. Sometimes its cellular texture is obliterated; the opposite surfaces of the vesicles and smaller air-tubes adhere together; the lung will not admit air: it looks like a piece of muscle, and is then said to be *carnified*.

Such is a general account of the anatomical characters of pleurisy, as they are disclosed to us by an examination of the body after death. We may now inquire what effect these changes are capable of producing on the *sounds* which are heard when the healthy chest is percussed, or listened at. We shall then be the better prepared to appreciate the several symptoms, general and physical, which are known actually to occur in pleurisy. Now it is clear that when the lung is pushed away from the walls of the thorax by fluid between the pleuræ, it will be compressed also; its capacity must be reduced; less air will be able to enter it. There will consequently be a proportional diminution in the intensity of the respiratory murmur; and this murmur will, moreover, be less audible in consequence of the distance, from the ear, of the structure in which it takes place. The lung is attached by its roots (so anatomists speak) to the spinal column. A moderate amount of effusion will, therefore, cause it to recede upwards and inwards: and a certain quantity of the liquid will ascend between the lung and the ribs, compressing the spongy pulmonary tissue around the larger and more resisting bronchial tubes. We might expect, in this condition of things, that the passing breath, and the voice, would be audible in those tubes, through the partially condensed lung, and through the circumfused layer of liquid: and it is so. We do hear bronchial respiration, and bronchial voice and cough; with some modification, indeed, to be noticed presently. In this respect,

therefore, you will observe that pneumonia, which solidifies the spongy texture of the lung around the bronchial tubes by filling it with lymph or with blood, has the same effect, so far as acoustic principles are concerned, as pleurisy, which solidifies a portion of the lung by expressing air from it, and pours round the bronchial tubes a fluid which readily transmits sound. Hence bronchial respiration and bronchophony are not always indicative of the same condition of parts within the chest, but derive their true value and meaning from the context, if I may so say; from the circumstances under which they occur, and with which they are associated.

When the effusion is so copious as to squeeze all the air out of the spongy part of the lung, to pack the organ up along the vertebral column, to distend the thorax, and to compress strongly the bronchial tubes themselves, *no* respiratory murmur *can* then be heard, nor any tubular breathing; for the dilated chest can neither expand nor collapse, and, therefore, no air can pass along even the larger air tubes; neither can these compressed tubes vibrate with the patient's voice; wherefore broncophony also ceases, or is but faintly audible.

Again, if percussion be made over a portion of the chest, beneath which, instead of healthy and spongy lung, there is incompressible serous fluid, a dull flat sound will be rendered. But a dull sound is rendered also when percussion is made over a solidified lung. Hence the mere dulness of the part struck does not inform us whether we have pneumonia or pleurisy to deal with, or some other disease that has the effect of making the lung solid, without plugging up the larger bronchi.

But an expedient presents itself, by which we may in some cases render this experiment of percussion conclusive. The dull sound occasioned by hepatization or other solidification of the lung occupies the same spot in every position of the patient. Not so, necessarily, the dull sound produced by the presence of liquid in the cavity of the pleura. The liquid will gravitate to the lowest part of the cavity, and will carry with it the dull sound. We place the patient, therefore, in different attitudes: and if we find the chest, when struck, resonant always in the higher, and dull always in the lower portions of the thorax, whatever its posture may be, then we may be sure that the cavity of the pleura contains liquid. In such a case, when the patient sits up, the dull sound will be elicited from the lower part of the chest, on one side, from the spine round to the sternum. When he lies on his back, the anterior of the thorax sounds hollow; the posterior dull: and when he reverses that position, and lies with his face downwards, these sounds change places also: the hollow sound is still uppermost, in the posterior part of the cavity; the dull sound still undermost, in its anterior portion.

There are just two states which may interfere with the true interpretation of the sounds produced by percussion in the manner now described; and these are, first, partial adhesions of the pleuræ, which may confine and isolate the effused liquid, and prevent its sinking from one part of the chest to another under the influence of gravity: and, secondly, so large an amount of effusion as to fill entirely the cavity and fix the compressed and empty lung in one position; for it is necessary, in order to obtain the shifting sounds in different attitudes of the body, that there should be light spongy lung to ascend, as well as heavier fluid to sink down, according to the posture of the patient. In this last case, that of excessive effusion, the whole surface of the affected side will yield a dull sound. It is seldom so in pneumonia: it is seldom that the entire lung on one side is so blocked up, in consequence of inflammation, as to give rise to universal dulness on percussion. But the diagnosis of these two conditions is an important one, and apt to puzzle a student. I hope to elucidate it as we go on.

We may now consider, with a better chance of understanding some of them, the *symptoms* which are generally met with in a case of pleurisy under its ordinary form and progress. The general signs, then, of that complaint are rigors, pain in the chest, dyspnoea, cough, difficulty or impossibility of assuming certain postures, and fever. Very much the same, therefore (as Cullen truly stated), with those of pneumonia, and, it may be added, with those of pericarditis: but auscultation differentiates these diseases. The physical signs I will examine presently. The general symptoms will bear, each of them, a short comment.

The *pain* which the patient feels—or the *stitch* in the side, as it is expressively called—is one of the most striking and characteristic signs of the disease. *Point de*

côté the French name it. It occupies a point or spot; and patients feel as if some sharp stabbing instrument were driven in at that spot every time that the act of inspiration goes beyond a certain limit. The Latin medical writers, attending chiefly to this prominent symptom, call pleurisy "*morbus lateris*."

This pleuritic stitch is subject to considerable variety in regard to its situation, its severity, and its duration. Most commonly it is felt on a level with or just beneath one or other of the breasts, in the part corresponding with the lateral attachments of the diaphragm: and this, even when the inflammation which occasions it is of much greater extent. Why is this? What is the cause of the pain? Wherefore should it be restricted to one small spot, when the inflammation pervades, it may be, the whole of the pleura? Pathologists have made attempts to explain these matters; but perhaps their explanations are not very much to be trusted to. They say that there is a larger amount of motion, at the lower part of the thorax, of the pulmonary over the costal pleura; and that the pain resulting from that friction, when the membranes are inflamed, is therefore felt where the friction is the greatest. However, the pain is not always confined to that spot. It is occasionally felt in other places, as in the shoulder; in the hollow of the axilla; beneath the clavicle; along the sternum; and sometimes it is complained of as extending over the whole of one side of the thorax. Andral states that he has observed the pain to prevail especially along the cartilaginous border of the false ribs, when the inflammation has attacked that portion of the pleura which covers the upper surface of the diaphragm. He says, too, that in such cases, the pain often affects the hypochondrium, and even extends as far as the flank, so that it might be mistaken for a symptom of abdominal inflammation. This observation is worth remembering. Sharp pain, occupying the right hypochondrium, belongs oftener to the pleura than to the peritoneum. I have known several instances in which such pain was erroneously supposed to be a sign of hepatitis, when in truth it resulted from inflammation of the pleura. Cruveilhier observes, also, that he has known the pain to affect the loins, and to simulate lumbago.

Whatever may be the situation of the pleuritic pain, it is generally increased by percussion, by intercostal pressure, by lying on the affected side, by a deep inspiration, by cough, and by different movements of the body.

In many patients the pain is exceedingly sharp, whether it be continued, or whether it occur only at intervals: the more *circumscribed* it is, generally the more *acute* it is. The patients are then in a state of great anxiety: they make very short and imperfect inspirations, through fear of aggravating the pain; they dread the least effort of coughing, or of sneezing, and suppress the desire to cough which the disease may occasion. There are other patients in whom the pain is moderate, is felt only when a *deep* inspiration is made, and is scarcely augmented by pressure or percussion. And there are even some cases of pleurisy which are unattended with pain from first to last.

The pain commonly exists from the very outset of the pleurisy. It is sometimes vague and fugitive at first, and becomes fixed and permanent after a day or two. In that case it may be mistaken for simple rheumatic pain; for pleurodyny; or for what is thought to be merely a nervous pain. When the pain is increased by slight pressure made *upon* the ribs as well as between them; when it extends over a large space; when it is unattended with fever; when it is inconstant or fugitive — we may *suspect* that it is situated in the fibrous and muscular tissues; but these circumstances do not afford any *certainly* that such is the case. In fact I have long been of opinion that some at least of the cases which pass under the name of pleurodyny, are really instances of what has been called *dry* pleurisy. You are aware perhaps that adhesions are very constantly found to exist between the lungs and the ribs in persons dead of pulmonary consumption. Such persons are liable to pains in the chest, beneath the clavicles, in the axillæ, between the shoulders, at the upper part of the dorsal region; in short, in those situations where the adhesions are found, after death, most frequently and in the greatest number. The pains indicated, it may be presumed, the periods at which the slighter forms of circumscribed pleurisy, attended with other effusion than that of coagulable lymph, took place. And it is probable that many cases of pleurodyny are really instances of the same kind of pleuritic inflammation. How often do we find, even when there are no tubercles in the lungs, firm adhesions between the pulmonary and costal pleuræ, in the bodies of persons who were never known to have had any pectoral disease! The pain alone marks the inflammation in those

cases; adhesion presently ensues; there is no fever perhaps, or none that attracts much notice; the pain soon subsides, and is soon forgotten; but the adhesion, the consequence of the inflammation, remains: and this is a morbid condition which is neither revealed to the sense of hearing, nor in any other way. I am much disposed therefore to agree with Cruveilhier in thinking that "*pleurodyne is nothing else* (in many cases at least) *than adhesive pleurisy.*"

I need scarcely repeat the fact which has so many times before been mentioned in these lectures, viz., that the inflammation of membranous parts, and especially of serous membranes, is attended with much more pain than inflammation of parenchymatous parts. We cannot have a better example of it than is afforded in most cases of pneumonia. Most cases of pneumonia are accompanied in the beginning with a stitch in the side; some cases are not. In those cases in which the stitch happens, the pleura also is inflamed to a certain degree, and the pain depends upon the coexistence of the pleurisy: they are cases of pleuro-pneumonia. In pure pneumonia, on the contrary, the pleurisy being wanting, the sharp pain is wanting also.

The respiration in pleurisy, at its outset especially, and while there is still pain, is considerably embarrassed; the movements of inspiration in particular are short, hurried, and often interrupted or jerking. And this depends evidently upon the pain, which forbids the free contraction of the muscles that dilate the thorax; and you may often observe that the dilatation is sensibly less on the affected side than on the other. Cruveilhier indeed denies this; or rather he states that he has never observed it: but it certainly is not an uncommon phenomenon. I have noticed it and drawn the attention of others to it, again and again.

When effusion has taken place—that, one can easily understand, will be likely to aggravate the dyspnœa; and it will aggravate it in a greater degree, or in a less, according to circumstances. Thus, if the *other* lung happen to be a diseased lung, then the compression of that which is on the side of the pleurisy will have a more injurious effect upon the breathing. The dyspnœa arising from the effusion and consequent pressure upon the lung will also be in proportion, first to the *amount* of the effusion; and secondly, to the *rapidity* with which it has taken place. When the effusion has been slow—or when it has long existed, and the case has become chronic—the circulation through the lung has had time to accommodate itself to the altered condition of the parts, the disturbed equilibrium between the quantity of air and the quantity of blood in the lung is restored, and the dyspnœa is consequently slight.

But there are very singular exceptions met with to all this. Andral states (and I have seen more than one instance confirmatory of his statement) that there are persons, with pleuritic effusion enough not merely to fill but to dilate that side of the chest on which it exists (and you will observe that we cannot doubt about the presence of the effusion in such a case), who appear nevertheless to be quite free from dyspnœa; and *that*, not while they are at rest merely, for they talk, get up, walk about, even take long journeys, without their respiration becoming so short as to make them complain of it. Now this is conceivable enough in old and chronic cases; but Andral further affirms that this absence of dyspnœa is not restricted to those cases in which the collection of fluid has taken place slowly; but sometimes happens, even in patients in whom pleurisy has led to abundant effusion in a few days. He gives a case of this kind, in which the patient was not prevented by an enormous pleuritic effusion from carrying on, without fatigue, in the streets of Paris, his business as a carter. I remember having a butcher in the Middlesex Hospital in exactly the same predicament; and nothing could persuade him that he was otherwise than well, and fit to go out; and out accordingly he went. Remember, therefore, that there are great varieties in this respect. In some patients the dyspnœa never ceases to be urgent from first to last; and these are apt to prove fatal cases. In others the respiration is very much impeded at first; then the difficulty of breathing diminishes; and at length it ceases, long before the fluid is reabsorbed. In others again, by some unaccountable idiosyncrasy, the respiration remains at all times very facile, both at the outset and during the progress of the disease.

Cough is another of the ordinary symptoms of pleurisy. It does not occur in paroxysms. It is small, half-suppressed, ineffectual. In some few cases this symptom also is entirely absent, even though the inflammation is intense, and the effusion into the pleura considerable. When cough does exist it is dry; or it is accompanied by

the expectoration of slight catarrh. If much frothy mucus should be expectorated, the pleurisy is complicated with bronchitis; if rust-coloured sputa be brought up, it is complicated with pneumonia: and in each case other signs, proper respectively to those two diseases, will be present.

A good deal has been said and written respecting the position which a patient assumes who is labouring under pleurisy. The manner of the *decubitus* has even been regarded as one of the pathognomic signs of the disease. Yet, strange to say, observers are much at variance with each other in respect to this so-called pathognomic symptom. Some affirm that the patient lies on the side affected; others that he can lie only on the sound side; others again that he lies neither on one side nor on the other; or even that he lies indifferently in any posture. But this dispute is an exact counterpart of the celebrated quarrel which took place about the colour of the chameleon: "they all are right, and all are wrong." I believe that, if you narrowly inquire into the facts, they will be found to be somewhat as follows:—In the outset of the disease, while there is yet pain, the patient cannot lie on the affected side on account of the pain, which that position exasperates; he lies therefore on the sound side, or on his back; sometimes he is obliged to sit up. At a more advanced period of the disease, when the pain has ceased, and considerable effusion has taken place, he cannot lie on the sound side, because of dyspnoea: the dilatation of the chest on that side would be impeded by such a posture; and what is more, the effusion, lying uppermost, would press upon the mediastinum, and so further tend to restrain the expansion of the sound lung. But he is no longer prevented by pain from lying on the diseased side, and consequently he does, in some instances, take that position: but more commonly still, he lies in what Andral calls a *diagonal* posture; *i. e.* the patient is not on his back, nor on his side, but between the two; on his back, we may say, but inclining towards the affected side. Again, however the fact may be explained, it is certain that there are some few persons who lie indifferently on the back or on either side, without augmentation of the dyspnoea in any of these positions, though one side is choke-full of liquid.

Now, of the symptoms that we have hitherto been considering, the pain, the dyspnoea, the cough, the accommodation of position, there is not one which, taken alone, can be said to be strictly or absolutely pathognomic; or which indicates in a positive and certain manner the existence of pleurisy, or of pleuritic effusion. Yet when all, or several of them, occur together, they afford a degree of probability on these points almost equivalent to certainty. There are yet some other, and more conclusive signs, which either in themselves, or taken in conjunction with those already mentioned, render the diagnosis of pleurisy easy and sure. These signs are furnished by the size of the thorax on the affected side; by its forms and motions; and above all, as you will have anticipated, by percussion and auscultation.

I have already stated that in some cases, that side of the chest which contains the effused fluid becomes evidently larger than the opposite side. The ribs and their cartilages present that position which they assume during a deep inspiration: the intercostal spaces are pushed outwards and brought up to the level of the ribs; and occasionally fluctuation may be perceived in those spaces, through the muscles. When these appearances are observable, no doubt (or *scarcely* a doubt) can remain concerning the nature of the disease. This dilatation of the thorax on the diseased side is more common in old chronic cases than in the earlier periods of acute pleurisy; yet it *may* take place in a very short time. Andral declares that he has known it sometimes reach a great degree by the fourth or fifth day of the acute disease. You may satisfy yourselves that the side *is* dilated by measuring it with a string. Carry the string round the chest, upon a level with the extremity of the xyphoid cartilage, then fold it upon itself, and you will find that the half of it will more than encompass the sound moiety of the chest, and will not reach round the diseased. The diseased side may measure an inch, or an inch and a half, or even sometimes two inches, more than the other. But this measurement by a string is seldom necessary. The eye takes a very accurate estimate of the comparative volume of the two sides; and the obliteration of the intercostal spaces can only be ascertained by seeing or feeling them. It is necessary to remember that, in most persons, the right side is naturally somewhat the larger of the two.

I say when this dilatation is noticed, *scarcely* a doubt can exist of the true nature

of the case. Some time ago I should have said *no* doubt: but having myself mistaken such a case, and seen others mistake it, I introduce this slight qualification, although it is a thousand to one against another such instance occurring to puzzle or mislead the observer. My colleague Dr. Hawkins had a patient in the hospital, in whom this dilatation of one side of the chest was exceedingly well marked. It was the left side that was enlarged; the heart was evidently pushed over to the right of the sternum. This is another circumstance strongly corroborating our conclusion in such cases. The intercostal spaces were effaced, and the whole of that side was perfectly dull on percussion. The poor fellow had a very unhealthy aspect; and he had, some time before, suffered amputation of a leg, for what was understood to have been scrofulous disease of the knee-joint. It was not unnatural therefore that every one who saw him should have come to the conclusion that this was a case of empyema; of fluid, and most likely of pus, collected in the pleura, and very probably the result of the extension of scrofulous disease from the lungs. Under these circumstances, and inasmuch as his dyspnoea was not urgent, it was not thought right to take any steps for evacuating the presumed fluid. The case was pointed out to the pupils as a capital example of empyema. At length the patient died; and when his body was examined we discovered—what think you? not pus, nor serum, but a large red *solid* mass, in the centre of which, when it was divided, was still a red, but softer, pulsatious, half-fluid substance. At first it was thought to be cancerous degeneration of the lung; but it was soon noticed that the solid part was arranged in concentric layers, like those which are often seen in aneurismal tumours; and further research showed that the effusion had indeed once been liquid, for it consisted entirely of blood, which had coagulated in the manner I have just described. And the source of the blood was detected. A portion of two of the ribs had been destroyed by ulceration, and one of the intercostal arteries had thus been laid open. The lung was found uninjured, but totally empty of air, and pressed flat up against the mediastinum.

No precaution could guard against such a source of fallacy; and you are not likely ever to meet with just such another case: yet I have thought it sufficiently interesting to relate, in illustration of the subject immediately before us.

It is unfortunate, so far as the diagnosis is concerned (but not in any other sense), that dilatation of the thorax is far from being a constant symptom, even in cases in which the effusion is very considerable.

There is still a condition of the thorax to be described, which is the very opposite to this. When the effused fluid begins to be reabsorbed—and when some cause or other, generally the formation of adventitious membranes, prevents the lung from re-expanding and approaching the ribs in proportion as the fluid is removed—then of course the ribs *must* sink in, and approach the lung, to prevent that void which would otherwise exist between the ribs and the lung. Consequently that side of the chest on which the fluid has existed becomes narrower than the sound side. And the actual difference between the two will be augmented by the circumstance that, in such cases, an amplification of the sound lung, and of the cavity in which it is lodged, a true compensatory hypertrophy, commonly takes place.

This partial or general retraction of one side of the chest is not so much a sign of disease actually in progress, as of disease gone by; and it may exist without evident disturbance of the health, of any kind.

Persons who are thus affected have the appearance of being inclined towards the diseased side, even when they endeavour to hold themselves upright: and the deformity, for such it is, becomes manifest to the eye when the chest is uncovered. You see that the side is narrowed and shrunken. All its dimensions are contracted. It measures less, in circumference, by an inch or more, than the other side. The shoulder is depressed; the hypochondrium is tucked up; and the ribs are drawn close together. A patient of mine, whose chest had been punctured (a remedial procedure to be spoken of presently), and who drew off daily, with a syphon, pus which did not otherwise find vent, had such difficulty at last in introducing the tube between his ribs, that excision of a piece of the bone was contemplated by the eminent surgeon who had performed the operation. The effect of the atmospheric pressure is sometimes so great as to crook the vertebral column, and produce lateral curvature of the spine. This I have myself witnessed. And as one of the unseen walls of the cavity,

viz. a part of the diaphragm, is carried permanently up under the ribs, so another of the unseen walls, the mediastinum, is liable to be influenced by the tendency to contraction. The heart, which, when the *left* pleura is *distended*, is apt to be *thrust* over, beyond the sternum on the right, may thus, when the *right* pleura is *contracted*, be *dragged* into the same position. In the former case, the dull sound given out by the diseased side when struck, will transgress the mesial line and encroach a little upon the healthy side: in the latter, the resonance yielded by the healthy will transgress the mesial line, and encroach a little upon the diseased side.

The difference of the two sides is so striking, that, at first sight, an observer supposes it to be even greater than it is actually found to be by admeasurement. Yet I have met with this deformity, as Laennec declares that he also had done, in persons who were not themselves aware of its existence. Some of them have not even known that they had suffered any previous thoracic disease.

The conditions I have just been describing are *physical* conditions; and the signs they furnish are *physical* signs. I have still to speak of the remaining physical signs which are also *auscultatory* signs. What I have already said upon this subject in the present lecture will, I trust, enable you almost to foresee the kind of information which these signs afford in actual practice.

As soon as even a slight amount of effusion commences in the pleura, it is announced by a diminution of the hollow sound which percussion elicits in the healthy state. In proportion as the effusion becomes more considerable, the chest, when struck, gives a sound more and more dull. At first this flat sound is rendered opposite the lowermost depending part only of the cavity; and this, as I showed you before, forms one ground of distinction between the dullness on percussion in pleurisy, and in pneumonia. However, at length, the effusion augmenting, the dead flat sound may proceed from the whole of the affected side; and this forms another ground of distinction: for it is very seldom that the whole lung becomes so solid in pneumonia as to yield a uniform dead sound over the whole of one side of the chest. Either the dull sound is universal on one side, or it is not. If universal, it is not likely to be the result of solidification by pneumonia; or, I may add, by tubercles: if not universal, the dull sound will (except in some rare cases) shift its place as the patient alters his posture.

I may mention another ground of diagnosis, which may be of great assistance when the case is seen from the beginning. The dullness comes on much more quickly in pleurisy than in pneumonia. It has been noticed within twelve hours from the invasion of the disease. In living animals, a considerable quantity of serous effusion has often been very rapidly produced by injecting some slightly irritant matter into the cavity of the pleura. In pneumonia, the dullness is commonly later in its appearance. The induration of the lung is gradual; and so is the pneumonic dullness on percussion: the effusion of serous fluid is early and rapid; and so also is the coming on of the pleuritic dullness. Moreover, as I have just shown you, pleurisy may displace the mediastinum, and cause the *whole* sternum to give a dull sound. A hepatized lung will render *one-half* only of it dull.

The intensity or completeness too of the dull sound is generally greater in pleurisy than in pneumonia. In two days, or even in twenty-four hours, the whole cavity of the pleura on one side may be filled quite full; and the whole of the corresponding surface of the chest, from its base to its summit, will yield a sound (to use one of Avenbrugger's strong expressions) *tanquam percussi femoris*. It is very uncommon for such total and universal *matité*, as the French call it, to result from inflammation of the lung.

Again, in the outset of the disease, while there is yet little or no effusion, but when the pain is acute, the vesicular breathing is heard more faintly and feebly on the painful side than on the other. On that side also the walls of the chest are less forcibly expanded. But percussion, when the pain will permit of its being practised, gives the same sound on each side. It is clear that the sharpness of the pain causes the patient instinctively to expand the chest on that side as little as possible: and, consequently, the quantity of air that penetrates the lung in a given time is diminished, and the respiratory murmur is feeble.

As soon as effusion commences, the vesicular rustle is heard still less plainly on the affected side; and in proportion as the fluid increases, that rustle or murmur becomes more and more faint: and at the same time it becomes more distinct and noisy than

natural—*puerile*, in fact—on the sound side. And while the respiratory murmur is disappearing on the diseased side, and the spongy lung is becoming empty of air from the pressure of the augmenting fluid, and the larger bronchi are surrounded by compressed lung and by incompressible liquid, the bronchial sounds begin to be heard, which I formerly described—the bronchial voice, the bronchial respiration. But the sounds are not exactly the same as those which are heard in pneumonia. They are modified by the nature of the substances through which they pass. The voice, for example, is still bronchial, still the voice of a person talking into a tube: but it has a superadded character; it is trembling, quivering, thrilling, cracked, discordant. I strive in vain to convey to you by these epithets a notion of this remarkable modification of the voice. Laennec's happy similitudes may enable you to form a more exact conception of it. It is like (he says) the bleating of a goat; or, happier still, it resembles the voice of Punch. But when once you have heard the sound you will never forget it again. I presume that this modification of bronchophony (for such it is, and such I would have you consider it) is caused by the rapid undulations communicated to the effused liquid by the vibrations of the bronchi and condensed pulmonary tissue. The sound is usually most distinctly heard near the inferior angle of the scapula, the patient being in a sitting position. It disappears, or merges into pure and distant bronchophony, when the liquid exceeds a certain amount, so as to compress the bronchial tubes themselves, and to *damp* their vibration.

I would have you recollect, therefore, that *ægophony*, which is the technical appellation of the sound I have just been describing (goat-voice),—*ægophony* is nothing more than a species or variety of bronchophony; and the two run each into the other by such fine gradations, that it is sometimes difficult to say which it is we are listening to. When the quivering is strongly marked we may be certain that it denotes effusion into the pleura; when bronchophony only is heard, we cannot be sure, from that sound alone, whether there be indurated lung between the ear and the bronchi; or a liquid, and a portion of compressed and condensed lung: but other phenomena complete the diagnosis.

Do not forget that, when any modification of the voice is heard, or thought to be heard, on the suspected side, the sound of the voice in the corresponding part of the other side of the chest must be ascertained also. It is only by a *comparison* of the two sides that we can come to any safe conclusion; and that *comparison* becomes often a striking and most instructive *contrast*.

LECTURE LIII.

Pleurisy continued. Recapitulation of Symptoms; of Diagnostic Signs. Causes of Pleurisy. Pneumothorax; its Conditions and Signs. Treatment of Pleurisy. Empyema. Paracentesis Thoracis.

In the last lecture I enumerated the symptoms, general and physical, which are met with, more of them or fewer, in cases of acute pleurisy. I then considered them singly; it may be well to take a rapid recapitulatory view of them as they exist together or in succession, and compose the actual disease.

The outset, then, of pleurisy, is marked by sharp stabbing pain, most commonly situated beneath one of the breasts, and preceded or accompanied by rigors. These two signs, the stitch and the shivering, are sufficient of themselves to awaken a strong suspicion that pleuritis has set in. At the same time there are usually a dry cough; a dread of breathing; a catch or catch in the inspiration, which is curbed, so to speak, by the pain; fever; often a comparatively feeble respiratory murmur on that side on which the pain is felt; and the patient cannot lie on that side. If no liquid effusion take place, these symptoms ordinarily disappear at the end of a few

days, and the patient recovers. The case has been a case of dry pleurisy; and the chances are much in favour of the lung having become permanently adherent to the ribs.

I should have said, with respect to the *fever*, that at the outset of the pleurisy it is often high. And it was matter of observation long before the method of auscultation was thought of, as well as since, that in the acute period of the disease the *pulse* is remarkable for its hardness, and forms a contrast with the softer pulse of pneumonia, and with the small and contracted pulse of inflammation of the serous membranes of the abdomen. Indeed the older physicians laid great stress upon the quality of the pulse, in their endeavours to distinguish pleurisy from pneumonia.

But to resume the description of the symptoms of pleuritis. Where effusion takes place (and it does so very early, so as to form a part of the complaint, just in the same sense in which expectoration forms a part of catarrh), the sound elicited by percussion becomes dull on the side on which the effusion exists. While the effusion is moderate, the dulness shifts its place according to the posture of the patient, and is heard only when the lowermost part of the chest is struck. But the fluid may soon increase so much as completely to fill the pleura; and then the whole of that side is dull. Meanwhile the murmur of respiration becomes feeble and faint, and at length, as the effusion augments, ceases altogether; while on the sound side it grows noisy and puerile. Tubular breathing, and that modification of the bronchial voice which medical men have agreed to call *ægophony*, become audible during the early periods of the effusion. *Ægophony* is heard, however, only so long as the quantity of liquid poured out observes a specific limit. There must be a certain amount of effusion—and there must not be more than a certain amount. I have sometimes thought that the discordant sound might depend upon the propagation of undulations through successive media of different densities. It certainly is somehow connected with the presence of a stratum of liquid between the lung and the ear. When the lung is strongly compressed, and especially when the cavity is stretched and distended by the enclosed fluid, the side is necessarily motionless; no tubular or other breathing can any longer be heard, or even occur: nor is the voice conducted, except perhaps very faintly, to the listening ear of the physician.

When the effusion is great, that side of the thorax on which it has taken place becomes, often, more or less dilated; and I should add, that the integuments on the same side are frequently oedematous. The patient now cannot lie on the sound side: and the most common posture is that which is intermediate between the supine position and the lateral; he lies *towards*, but not, in general, *upon*, the affected side.

I observed, in the last lecture, that this inability, after the effusion has reached a certain point, to lie on the sound side, might be accounted for in two ways. Partly it may be owing to the impediment which lying on the sound side offers to that side's expansion. The muscles which dilate the healthy side have then to lift, as it were, the weight of the body, and are, some of them, pressed upon and incumbered in their action, by that posture. But the inability in question is chiefly attributable to another circumstance, viz., the pressure exercised by the effused fluid downwards, through the mediastinum, upon the only lung that is left to perform the function of breathing. Now disputes, or differences of opinion, have arisen as to which of these two circumstances is the most efficient cause in this matter: and therefore it may not be amiss to provide you with the facts which prove that the last-mentioned cause is, in reality, the most operative—I mean the weight of the superincumbent liquid, in the supposed position, upon the mediastinum and upon the healthy lung below it. This is shown by the fact, that patients, to whom the decubitus on the sound side had previously been impossible, on account of dyspnoea, have been able to rest in that position *immediately after* the artificial evacuation of the fluid. Now in such a case the obstruction to the dilatation of the healthy side, produced by placing it under the weight of the body, would remain the same as before, or nearly so. A hospital patient of mine, named Coggs, could not breathe if he attempted to lie on his right side. His left pleura was distended by liquid effusion. I thought fit to have paracentesis performed: and the poor man was greatly delighted to find himself at once enabled by it to assume the posture which his weariness had long made him wish for, but which he had not been capable of enduring. We found, by percussion, that the diseased side was now filled with *air*; the compressed lung had not risen at all; so

that the necessity for the free expansion of the sound side was just as great as before the operation. You may find a precisely similar consequence of the same operation related in the fifth volume of the *Dublin Transactions*.

The œdema that is sometimes observed on the diseased side is more or less connected, probably, with the habitual position of the patient.

There is yet another sign of pleuritic effusion, which, as it is very simple, and readily perceived by even the least instructed observer, is too valuable to be neglected. In most persons, one's open hand, laid flat upon the surface of the chest, feels the vibration or thrill which the voice occasions when the person speaks. Now, in a case of pleurisy with effusion, you will generally find a remarkable contrast between the two sides in this respect: *i.e.*, the thrill is strong and evident on the sound side, and not perceptible at all on the other. Whereas, when the whole side is dull in consequence of the solidity of the lung, the thrill is much *augmented* on that side. But this thrill is not always present in the healthy state, and then we can infer nothing from its absence on the diseased side. Its presence, however, under such circumstances, would indicate consolidation of some kind.

After a while, when the fever has ceased, the liquid begins to be reabsorbed: but as, in many cases, the lung is more or less bound down by adhesions, or overlaid by a membranous stratum of lymph, it cannot expand in proportion as the liquid is removed: and the necessary consequence is *that* shrinking of the affected side in all its dimensions which I fully described yesterday.

Let me now briefly re-state the points of distinction between pleuritic effusion and pneumonic consolidation, when the one or the other of these two morbid conditions is proved to exist by dullness on percussion, extending over the whole of one side of the chest. The question is one which frequently arises; and it is one of much interest and importance.

First, then, we distinguish these different conditions, having some physical signs in common, by their *history*. In pleurisy, sharp pains and a dry cough, or perhaps no cough, precede the dullness: and we have not the crepitation, nor the rust-coloured sputa, which are antecedent to the dullness of pneumonia.

We cannot, however, always learn the previous history of a given case.

Secondly, a lung rendered solid by inflammation does not *distend* the cavity. Copious pleuritic effusion most frequently does. In the first case, therefore, we have not that separation of the ribs, that obliteration of the intercostal depressions, that protrusion of the corresponding hypochondrium, that mensurable enlargement of the side, that extension of the dull sound beyond the middle of the sternum, or that displacement of the heart, which are, some or all of them, apt to result from a collection of liquid in the pleura.

Thirdly, the solid lung transmits the voice from the pervious bronchi to the surface of the thorax; and if any motion of the affected side remain, it transmits also the sound made by the passage of the air through them. These phenomena are wanting when the pleura is so stretched by its liquid contents as to make the side everywhere dull to percussion.

Fourthly, the vibration of the thoracic parietes, caused by the patient's voice, is augmented by consolidation of the lung; prevented when it is strongly compressed by imprisoned liquid. The increase of this thrill can be felt therefore in the one case; its diminution in the other.

This simple test fails to be applicable when, from the feebleness or the high pitch, of the person's voice, no thrill is perceptible on either side in the healthy state. Unless, indeed, disease should generate a vibration, which, in such a case, would certify solidity.

Fifthly, a patient having one lung solid, is generally indifferent as to posture. A patient having one pleura quite full of liquid, lies (usually) on or towards that side; and is distressed and suffers dyspnoea if he attempt to lie on the other.

It is of more importance that we should inquire into the *exciting causes* of pleurisy than into those which give rise to pneumonia. They are more numerous and complicated, and have a more direct bearing upon the prognosis and treatment in the one case than in the other. I do not desire to refine too much; and therefore I shall

restrict myself to those causes which are obvious, and which you are likely to meet with in practice.

I merely say of exposure to cold, as an exciting cause of pleurisy, that it is a very common—the *most common*—cause. You know already all that I can tell you of the circumstances that are likely to render that cause effectual in producing internal inflammations, and, among the rest, pleuritic inflammation.

But pleurisy is often occasioned by mechanical violence; or by the accidental extension of disease from other parts; and the course, and the event, of the disease, are liable to be considerably modified by the nature of its cause in such cases.

Pleurisy may be excited by the splintered ends of a broken rib; and if the pulmonary pleura be wounded in that manner, air may get into the pleural cavity, as well as into the areolar tissue beneath the skin; constituting the true and genuine *emphysema* of our forefathers. Pleurisy may be determined also by a penetrating wound of the thorax; or by a perforating ulcer of the pulmonary pleura, the extension of a tubercular excavation. In the one case air will enter from without, if the aperture be sufficiently large; in the other, air will pass from the lung into the cavity of the pleura. In all of these cases of air finding its way into this serous sac while in a state of inflammation, the event of that inflammation is much more likely to be the effusion of *pus*, than when no communication exists between the inflamed membrane and the atmosphere. This I have mentioned, and offered some explanation of, before. But another very curious consequence results from the admission of the air, and its coexistence with puriform or other liquids in the sac of the pleura. New auscultatory signs arise, very easily appreciated, very instructive, and therefore very necessary for you to be acquainted with.

You must know that when the pleura contains air alone, the patient is said to have *pneumothorax*; and when (what is infinitely more common) the air is there in company with liquid, he is said to have *pneumothorax with effusion*. This is the name given to that condition of the chest by Laennec; and it serves its purpose sufficiently well. I shall take leave to employ the simple term *pneumothorax*, in speaking of either condition; whether there be liquid also in the pleural cavity or not. *Pneumothorax*, then, often proceeds from one or other of those causes of pleurisy just mentioned. It is sometimes produced too by the operation of *paracentesis thoracis*; by the opening made into the thorax with the trocar of the surgeon, in order to let out its fluid contents; in plain English, by *tapping* the chest.

The modifications of sound that result are particularly curious. Of course the air occupies the higher portion of the cavity and the liquid the lower, in whatever position the patient may be placed. And this being the case, percussion will give a remarkably hollow sound when made upon the uppermost part, and a totally dull and flat sound when made upon the lowermost part: and the change from the hollow to the dull sound will often take place quite abruptly, so that you may trace out the exact level at which the surface of the effused liquid stands. And if you reverse the posture of the patient, the resonant and the dull sounds will interchange their respective places: the uppermost part always yielding the clear, and the undermost the flat sound. This is just what you would expect. The result of the experiment is the same whether you make it upon the human thorax, or upon a beer-barrel. The resonant part, you are to observe, will be much *more* resonant than it would be in health—more resonant (you have always the other lung to test it by) than the corresponding portion of the opposite side of the chest—tympanitic, drum-like; for the air is not involved in spongy lung, but contained in a free space: and the sound is not damped, as in a healthy chest it is damped somewhat, by the *presence* of the lung. Moreover no respiratory murmur can be heard where this tympanitic resonance occurs: nor can any thrill be felt. Now I say all this is no more than you must have foreseen. But the sounds detected in this new condition of things by the ear applied to the chest, as the patient *breathes* or *speaks*, or *coughs*, you would *not*, I think, have anticipated. You hear then a sound which I must endeavour to describe in words, but which you will scarcely form a right conception of till you have heard it, and then all further verbal description will be needless. I can describe it by similitudes only. The patient's breathing is like the noise produced by blowing obliquely into an empty flask; and so the French have given the sound the somewhat magnificent title of "*amphoric resonance*." I have heard, fifty times over, exactly the sound in ques-

tion when I have been out shooting in a gusty day, and the wind has blown sideways into the gun-barrel. It is a ringing, metallic sound. When this is present during the *breathing*, the *voice* also has, even *more strongly* in general, this metallic character; and so has the *cough*; and each of them is apt to be succeeded by a tinkling echo. The voice, and cough, resemble those of a person who speaks or coughs into a deep well: or with his head bent over an empty copper boiler. The same ringing quality is often heard when one speaks in a large vaulted room; or beneath the arch of a stone bridge. You may perhaps now have some idea of what these metallic sounds are. They are very singular: and they are perfectly decisive (as far as my experience has gone) of the presence of air in a considerable cavity, within the thorax; which cavity mostly contains liquid also: and of the presence of air and liquid in the cavity of the *pleura* in particular. I do not know that the liquid is essential: I do not believe it is; but commonly there is some liquid, and a good deal of air. Almost always, too—but *that* is not indispensable—the cavity communicates with the external air, either through the walls of the chest, or through the bronchi. Neither is it necessary that the cavity should be in the pleura, for it may be in the lung: and when we come to speak of phthisis, I shall point out the circumstances which may enable you to determine whether the sounds proceed from a tubercular cavity, or from the sac of the pleura. What you will please to remember is that, in actual practice, in ninety-nine cases out of a hundred, these sounds will be found to denote the presence of both air and liquid in the cavity of the pleura; and the probable existence of some passage of communication between that cavity and the *external* air: in a single word, they will reveal the existence of pneumothorax. The voice reverberates in the little cavern just as it does in a large empty room with a stone roof; and this is the best explanation I can give you of the phenomenon. Sometimes, as you are listening, especially if the patient have recently changed his posture, you will hear a sound just like that occasioned by dropping a pin's head into a glass vase, or into a metal basin: and to this sound the name of *metallic tinkling* has been given. It really often closely resembles the distant tinkling of a sheep-bell. This is supposed to result from the dropping of the liquid from the upper part of the cavity; or sometimes from the bursting of a bubble on the surface of the liquid during respiration. You may succeed now and then in hearing a species of the same metallic tinkling by applying the stethoscope over the stomach, when percussion has already taught you that it is distended with gas, and by getting the patient to swallow some drink in successive teaspoonfuls.

Another auscultatory sound, arising out of the same condition, viz., the presence of both air and liquid in the cavity of the pleura, and known even as early as the time of Hippocrates, is rendered audible by *succussion* of the patient's body. You lay your ear upon his side, and get him to give his body a sudden jerk or jog: or you get some one else to take him by the shoulders and shake him; and you hear the liquid splashing within: just as you hear it when you shake a cask that is neither full nor empty of water. This is an unequivocal indication of pneumothorax; and demonstrates beyond a doubt that there is both air and liquid in the pleural sac; for no sound would arise if there were liquid only. A moderate quantity of liquid will make a greater squash than a large quantity. Unequivocal I say it is, because one could scarcely be misled by the splashing which may sometimes arise from wind and water mingling in the *stomach*. I wish that a patient, who was under my observation for some months last year in the Middlesex Hospital, and could produce this splashing noise at will, were there now; for he was not a little proud of his fatal gift, and I should have brought him down here to-day, and given you an opportunity of hearing this sound for yourselves, worth a dozen descriptions of it.

It is surprising how long this state of things within the thorax may last, without any great declension of the patient's general health and strength, even when the disease is (as it mostly is) incurable. Two men, patients of mine, both of whom had well-marked pneumothorax in connexion with tubercular phthisis, remained in the hospital for several months; till, in fact, I could conscientiously keep them there no longer: and each of them went away in very tolerable plight. I was unable to trace them afterwards, for they returned to their homes, the one in Ireland, the other in the north of Scotland.

In June, 1853, I was consulted upon the case of a lady in whose right chest, near

the angles of the ribs, just below the scapula, the physical signs of pneumothorax were strongly pronounced; amphoric breathing, amphoric voice, metallic tinkling, and a splash following succussion. This last sound I and others often heard, while standing near her, without any application, direct or mediate, of the ear to her chest. It was audible by herself when she was jolted in a carriage, and when she cantered on horse-back. She first heard the internal splashing, while cantering, in June, 1852. In November of the same year she had borne a child. Under cod's liver oil she grew strong and stout, and could take a good deal of horse exercise. She died, rather suddenly, at a distance from London, in January, 1855.

In this instance pneumothorax existed at least two years and a half; probably longer. The patient began to cough in 1851.

You see, then, that the conditions of pleurisy, and the symptoms of those conditions, may be modified by its causes. All those causes that imply the introduction of air into the cavity of the pleura, imply also a more serious state of disease than results from most other causes. The perforation of the pleura by the extension of a vomica, I have mentioned as one of those causes. But tubercles in the lungs are frequently, very frequently, the cause of pleurisy, when no such perforation has taken place. A tubercle, or a group of tubercles, approaches the surface of the lung, but does not break through. Generally the pleurisy so produced is slight and partial, and ends in the formation of adhesions: it is *dry* pleurisy. And this very common occurrence of adhesions between the costal and pulmonary pleuræ, in the course of tubercular disease of the lungs, is, in truth, one reason why *perforation* of the pleura, and pneumothorax from that cause, is comparatively so rare. The part where the perforation is likely to take place has generally, though not always, been secured and clouted, as it were, by previous adhesion. So that even here we find that inflammation has a conservative tendency, and helps to postpone the fatal ending of the specific disease.

Pleurisy may terminate in resolution and complete recovery; or in adhesion, which is its next best termination, and which obtains for the patient, at the expense of some trifling embarrassment of his breathing, complete security for the future against the dangers of pleuritic effusion. Again, acute pleurisy may end in chronic disease of the pleural cavity: *i. e.*, in a shrinking inwards of the walls of the chest, attended with total uselessness, or a very imperfect and limited use, of the corresponding lung. Lastly, pleurisy may terminate in death. It may cause effusion so copious, that the patient will die of actual suffocation, unless the fluid be removed by art. On the other hand, he may die worn out and exhausted by the disease, especially if it be attended with suppuration. In that case he will suffer hectic fever, and all its wasting and mournful accompaniments; and death ultimately by asthenia. It is seldom that simple idiopathic pleurisy proves fatal.

As the matter from a tubercular cavity may break *in* upon the pleural sac, and lead to the admission of air, and the establishment of pneumothorax; so the puriform fluid which has resulted from inflammation of the pleura, and was for some time imprisoned in its sac, may also break *out*, and the result will still be the admission of air, and pneumothorax. This is not a very frequent result of pleurisy, however. When it occurs, an abscess forms externally, generally in front of the chest; and either the abscess bursts, or it is opened by the surgeon, and then it is found to communicate with the cavity of the pleura.

Sometimes air is effused into the sac of the pleura, in consequence of the rupture of dilated air-cells on the surface of the lung; of this accident of disease I may refer you to an instance related by Dr. Lloyd, in a paper upon pneumothorax, contributed by Dr. Hughes to the eighth volume of the *Guy's Hospital Reports*. Sometimes gas is generated within the sac, from the decomposition of effused liquids, or of a gangrenous lung; and in such cases the gas has a strong odour, like that of sulphuretted hydrogen: sometimes, again, gas is said to be secreted from the membrane itself. All these events are, however, uncommon. When air, from whatever source, is shut up in the cavity of the pleura, and goes on accumulating there, it will compress the lung, just as certainly and effectually as if there were a liquid extravasated. And such compression, if suddenly brought about, may cause speedy death by apnoea: and this is more apt to occur from a scratch of the pulmonary pleura by the rough edge of a fractured rib, than from any other cause.

As to the *treatment* of pleurisy, you will have anticipated that in the outset of the disease we must have recourse to the lancet. I have stated, more than once, that blood-letting *tells* more, and is better borne, in inflammation of serous membranes, than in any other case. If you see the patient while the stitch in the side, and the restrained and cautious respiration are present, you will bleed him, in the upright posture, from a large orifice, until the pain is relieved, and he can draw a full breath again with ease and satisfaction; or until he is about to faint. And if the pain and catch in the breathing should return, and the pulse continue firm and hard, you will repeat the blood-letting; or cover the painful side with leeches; or abstract blood by the cupping-glass and scarificator. It is best to bleed fearlessly at first; and in proportion as you do so, the chance will be diminished of a repetition of the blood-letting being needed. The blood drawn in pleuritis is always deeply buffed and cupped.

Observe that I am here speaking of acute pleurisy, occurring in a person previously sound and healthy. If there have been any chest symptoms before, if there be any suspicion of tubercle, even if the patient be delicate, or of a consumptive family, or very young, or very old, you will do well to restrict yourselves to *leeches*.

Tartar emetic, which is so useful when the mucous membrane of the air-passages is inflamed, is *not* adapted to inflammation of the pleura. On the other hand, mercury, from its well-known power to check the effusion of coagulable lymph, is *especially* indicated. Of course it is to be given with a view to its specific effect on the system: *i. e.*, in equal doses, repeated at frequent and equal intervals, and guarded by a small quantity of opium. And in very severe cases, or when the internal employment of mercury is in any way contra-indicated, recourse must be had to inunction of the linimentum hydrargyri, or of the strong mercurial ointment.

By the early and vigorous adoption of these measures, the inflammation may generally be subdued in no long time. If, though the fever diminish, there still be pain in any part of the chest, leeches may be again applied, or the part may be covered with a blister. I do not think a blister does any good,—on the contrary, it is likely, by the additional irritation it causes, to do harm—while the inflammation is yet recent and active.

But though pain may have ceased, and no fever remains, and the patient is not conscious of much dyspnoea, there may be, and there often *will* be evidence, not to be mistaken, of effusion into the cavity of the pleura. Dulness, I mean, on percussion, bronchial respiration, ægophony; and the object of our treatment is now to get rid of the fluid. We seek to do so by keeping the patient on low diet. The more (says Broussais, with some quaintness), the more a patient eats, the sooner he will die. We pursue the same object by keeping his gums tender with mercury; by applying blisters one after another to the affected side; and by purgatives and diuretics. By keeping the vessels empty we facilitate, as much as in us lies, the absorption of the liquid contents of the pleura. A very good form of diuretic for this state of matters is a combination of squills, digitalis, and mercury. Half a grain of digitalis, one grain of squills, and three or five grains of blue pill, repeated and continued according to the state of the mouth.

Under this kind of treatment the effused fluid will often be completely removed; and the chest restored to its former state. I last week dismissed a lad from the hospital in whom all this was accomplished.

But in other cases, though the fever and the inflammation are at an end, and absorption of the liquid takes place, the parts within the thorax do *not* revert to their original condition. This we know by that shrinking of its dimensions on the side affected, which was described in the last lecture. This shrinking and narrowing is the *necessary consequence* of the absorption of the liquid, *unless* the compressed lung dilates again in proportion as the fluid is taken up. In many cases of this kind the lung *cannot* rise; being bound down by thick and firm false membranes: and then the deformity is irremediable, and lasts for life. If the lung be completely emptied of air, and enveloped by strong bands of lymph, so that it is permanently unable to admit air again—in that case, as the bony framework of the thorax can yield to a certain extent only, there will always remain, I presume, some liquid in the pleural cavity. If, again, the lung recover a part of its lost volume, and *meet* the contracting parieties of the chest, adhesion may take place; and the cavity of the pleura be obliterated by thick layers of false membrane. And other changes are apt to arise in

the lymph which is adherent to the pleura in these cases of imperfect repair. Sometimes tubercles form in it. Sometimes ossific matter is deposited. I show you a fine specimen of this kind of ossification of the pleura. There is yet another supposable case: the investing adventitious membrane may be thin and weak, and yielding; and though the lung may not expand to its full dimensions at first, it may gradually force its way against the binding power of the coagulable lymph, and then the external configuration of the chest may be restored, and the symmetry between the two sides return. That this sometimes takes place I cannot doubt: but I have only met with two cases in which the dwindling of the side was *entirely* recovered from. In May, 1834, I was asked to see a child four years old, who had had cough, and had wasted to mere skin and bone, after scarlet fever. I found the whole of the right side of the chest perfectly dull on percussion, and no respiration could be heard on that side. He was taken by his parents into the country, and I did not see him again for some weeks. He then had ceased to cough, and, in a great measure, had regained his strength; but he presented on the side which had been dull, as marked and complete an example as I ever saw of that sinking in of the ribs, with flattening and contraction of the chest, and depression of the shoulder, which denotes bygone pleurisy, and diminished bulk of the lung. About a year from the occurrence of the original disease his father brought him to my house, that I might see the change which had again taken place. The boy was plump and rosy, and in perfect health; the right side of the chest was as full and round as the other: the symmetry of the two sides was completely restored; the breathing natural and perfect; and the sound on percussion hollow. His father, to whom the former shrunk state of the side had been pointed out, told me that he had watched, with deep interest, the process of recovery, and that it had been very *gradual*. The only other example of perfectly regained symmetry that I have seen, occurred in the person of an adult man. I shall tell you some particulars of this remarkable case presently.

There are yet other cases in which the effusion continues and increases, and the side, instead of shrinking, enlarges; the functions of the lung on that side are entirely abolished; nay, the use of the remaining lung is greatly interfered with, by the pushing over of the mediastinum; and the patient is in imminent danger of suffocation. In such cases, whether the effusion has taken place rapidly or slowly—whether the disease has been acute or chronic pleurisy—we must relieve the oppressed lung by *letting the fluid out*—by tapping the thorax; and the sooner that is done, when such a state of things exists, the better.

The operation is not difficult, nor formidable; but a mistake in the diagnosis may be *very* formidable. I have heard of two instances, one in Scotland, and one in this town, in which the operation of paracentesis thoracis was determined on, to relieve the oppression caused by empyema: but the opening was made on the wrong side; and the patient in three minutes was, in each case, a corpse. There was effusion, which had already put a stop to the play of one lung; and upon air being freely admitted to the surface of the other, it collapsed also, and immediate suffocation took place. I do not mention these mishaps to deter you from performing the operation. They both took place some years ago. Such a mistake would be unpardonable now. But I mention them to show the necessity of our being sure of our ground before we proceed to open the thorax of a living person. A surgeon once told me that, with the sanction, and at the suggestion of a physician, who understands auscultation exceedingly well I believe, he passed a trocar into the chest of a patient; but no fluid followed, to the no small mortification of the physician. This proved to be a case of malignant disease of the lung; and fluid was let out afterwards by puncturing the thorax in another place, and much relief afforded; although of course the disease proved ultimately fatal. The surgeon informed me that he had suspected the true nature of the case, from observing a livid protrusion in front; which was, in fact, the specific disease making its way through.

You will take care, then, to survey the chest narrowly before you plunge a trocar into it. If you see by your eye, and ascertain by measurement, that one side is larger than the other; if the intercostal depressions be effaced on that side; if the whole surface afford a dull sound when percussed; if the side do not move at all, or scarcely move during respiration; if no vibration can be felt on that side when the patient speaks; if no breathing can be heard in the corresponding lung; if the heart be

found beating in an unnatural place, down towards the left hypochondrium, or in the other direction on the right of the sternum; and if, at the same time, the other side of the chest shall move freely, sound resonantly, communicate a thrill to the hand while the patient converses, and be full of *puerile* respiration; then you may be sure that the larger side is distended with fluid.

But it does not follow that you should, therefore, open that side. The propriety of doing so will depend upon circumstances.

There are two objects for which the operation of *paracentesis thoracis* may be contemplated; and these it is well to keep distinct. It may be curative in its intention, or merely palliative. In cases of simple pleurisy it may be adopted with the view of saving life, and restoring health. Again, when pleuritic effusion is complicated with other and mortal changes, the operation may sometimes be resorted to for the purpose of relieving urgent distress, and of prolonging, it may be, a doomed existence.

In simple pleurisy it ought never, in my judgment, to be performed unless the life of the patient is, or seems to be, in jeopardy, from the continued presence of the liquid within the thorax.

Now life is plainly in jeopardy when the vital functions of the lungs, or of the heart, are greatly hindered; when symptoms present themselves of approaching death by apnoea, or by syncope. If we discover no cause for those symptoms, except the increasing pressure of liquid, or of air, pent up in the pleura, we are warranted in ascribing them to such pressure, and bound to act upon that persuasion. Whenever, with the physical signs of abundant effusion, we have great hurry and distress of breathing; an anxious and livid aspect; a tendency to delirium—or extreme faintness, and a vanishing pulse—there is no time to be lost: it is our duty to propose and to urge the mechanical removal of the pressure which must else be fatal.

Again, when the patient, without suffering much dyspnoea while he lies quiet, is yet evidently losing ground from day to day, and early death by *asthenia* appears to be inevitable, without the operation; and when all other means for getting rid of the imprisoned liquid have failed; and when no other condition of disease, or of advanced age, exists to account for the progressive sinking; then, also, in my opinion, the patient should not be denied the *chance* which the operation may afford.

Thirdly, whenever (no matter how we ascertain the fact) the effused liquid consists of *pus*, it should be let out.

In either of these three predicaments of simple pleurisy, and in no other, should we be justified (as I think) in making an opening into the living thorax.

But I wish to be understood as giving you simply the impression which my own experience has made upon my own mind. I know that some practitioners recommend the early employment of the trocar; while (they say) the false membranes, which are apt to prevent the compressed lung from expanding again, are yet tender and unorganized. But surely we should risk much, and gain nothing, by admitting air into the pleura while the inflammation is still in progress. Most cases of mere pleurisy with effusion do well. The mortality from uncomplicated pleurisy is exceedingly small. It would, I fear, be vastly augmented if every patient having manifest effusion were to be tapped. The danger of the operation is this;—that it may, and probably will, induce suppuration, or cause the effused liquid to become putrid. Generally the effusion consists of serous fluid, which is at length spontaneously reabsorbed; the lung expands again, or the walls of the chest shrink inwards: and the ultimate state of such a patient is as good as it probably would have been after a successful tapping.

To make assurance doubly sure, it is always right, before proceeding to the operation of *paracentesis*, to adopt the expedient first suggested and used, I believe, by Dr. Thomas Davies, of trying the chest by means of a grooved needle; making a tentative exploration of the nature of its contents in that manner. The passage of this little instrument—like the dismissal of a pilot balloon—affords information which is useful in guiding the particulars of the subsequent process. As a mere diagnostic measure it is highly valuable. It not only ascertains that there really is liquid within the pleura, but it discovers the kind and quality, and exact place of the liquid. If it be serous, it will flow readily along the groove, and trickle down the patient's side. If it be puriform and thick, it will not exude so freely, but a drop or two will probably be visible at the external orifice: and when the needle is withdrawn, its groove

will be found to contain pus. In the former case it is possible that there may be no false membranes; in the latter they are likely to be thick. You would use a larger trocar to evacuate the thicker fluid.

The puncture thus made is quite harmless; and inflicts very trifling pain. Dr. Davies gives this useful piece of advice in respect to the trocar, that its point should be *sharp*: for otherwise, after the serous membrane has been penetrated, if there happen to be thick tough layers of coagulable lymph, not very closely attached to the costal pleura, they may be driven before the instrument, and so the liquid will not be reached, but the operator will be perplexed and baffled.

Connected with the operation itself there are some questions concerning which medical opinions and medical practice are not yet settled. I do not pretend to decide these questions: yet I cannot pass them by. I must point them out to you; and I shall, at the same time, state what my own observation has suggested in regard to them.

1st. Should all the liquid be let out at once?

Some say yes: some say no. If we appeal to experience on this point, we obtain no satisfactory answer. I have known patients get rapidly and perfectly well, after as complete an evacuation of the liquid as was possible. On the other hand, I have heard of speedy recovery when, by a sort of accident, very little had been withdrawn: enough to relieve the pressing distress: but much less than the operator intended.

We must try the matter, therefore, by our reason.

I think it very probable that when the serous membrane is *stretched* by the pressure of its contents, its natural absorbing power may be lessened. But we have no reason to suppose that the mere relief of this tension will *often* suffice to renew the process of absorption, and to enable the flattened lung to re-expand.

The theoretic objection to the thorough emptying of the thorax in such cases is (I conceive), that the introduction of air is likely to be hurtful, by converting the adhesive into the suppurative form of inflammation, and by promoting decomposition of the extravasated fluids. No doubt there is this risk; but, in general, if you wish to empty the pleura, it cannot be avoided. Unless the lung rises freely at once, the liquid *cannot* all, nor even much of it, come out, without air getting in. But the mere admission of air into the pleura does not necessarily *create* inflammation of the membrane. This we know from what happens sometimes in emphysema produced by a fractured rib. In the only instance of *pure* pneumothorax which I ever saw, the sac of the pleura had become half filled with air, through a very minute opening in the pulmonary membrane, communicating with the air-passages. There was no inflammation of the pleura in that case. Except that it was preternaturally *dry*, it seemed perfectly healthy. Neither does the access of air necessarily superinduce suppuration in the membrane already inflamed. Certainly, if pus follow the passage of the instrument, as much should be removed as we can get. And, for my own part, I should take away as much as would come, whenever the inclosed liquid proved to be serous. If much be left behind, a repetition of the operation will commonly be required. Air disappears spontaneously with far greater readiness than serum; and opposes less resistance, while it remains, to the gradual re-expansion of the compressed lung. Should you desire however to evacuate, as some advise, so much of the liquid, and no more, as the expansion of the lung, and the elastic resilience of the thoracic parietes suffice to press out, without admitting air—that object may be insured by adopting a very simple contrivance of Professor Schuh's, of Vienna, which was recently shown me by Mr. Spencer Wells. It consists of a sort of small trough, which is readily fitted to the end of the canula after the trocar has been withdrawn, and which is provided with a valve that prevents any reflux of liquid, or passage of air, from the trough into the canula. In this way the entrance of air into the pleural sac may be effectually obviated.

2ndly. Is the orifice to be healed up, or to be kept open?

Here, also, practical men differ. I should say, if pus come out, by all means make the aperture large, and keep it open; and inasmuch as detention of the pus would be injurious, and the depending point is difficult to hit, and the orifice is apt to clog, I would do more than leave it open: I would draw the puriform fluid off twice a day by a syphon.

If serum be let out, by all means close and heal the wound. Then, if all go on well, our object is achieved. But should the condition of the patient fail to improve; should hectic fever, after a day or two, set in or even continue; should much constitutional distress or disturbance arise;—under such circumstances I would reopen the wound. There *was* mere serum, or liquor sanguinis; there now *is*, in all probability, puriform matter pent up in the pleura; and even stinking and poisonous gases.

On six occasions I have myself witnessed the evacuation, by puncture, from the human pleura, of a clear transparent liquid. Some of the patients were under my own charge, some under the charge of others. Of these six patients one died the day after the operation; I can scarcely say why. She was an extremely timid and susceptible young woman; and I am inclined to attribute her death to the shock produced, by apprehension of the operation, upon her sensitive nervous system. Two others recovered forthwith, and perfectly. The wound presently healed in the three remaining cases also; but in one of the three it soon broke out again, and a quantity of healthy pus was discharged daily. After some time, the expedient of keeping the cavity free from accumulated pus by the use of a syphon was resorted to. Under this plan the discharge became gradually less and less, and at the end of many months it finally ceased. The side at one time was so shrunk in, and the ribs were drawn so closely together, that the introduction of the syphon became difficult. Ultimately this deformity was removed, and the symmetry of the chest restored. When the patient presented himself to me, after two years' residence upon the Continent, I found both sides of his thorax alike in shape and dimensions, and the pulmonary expansion everywhere audible and natural. This gentleman continues now (1857) in the enjoyment of perfect and vigorous health. This was the case to which I just now referred as forming the second example that I have seen of the complete re-expansion of a side contracted after pleuritic effusion. When the operation was performed, eighteen years ago, the patient was gasping, livid, faint, and on the brink of perishing by suffocation; it gave him instant and lasting relief. I have been told of a man who, for the last fifteen years, has had a similar thoracic fistula; and who has, nevertheless, during nearly the whole of that period, been actively engaged in the various labours of a farm-servant.

I have still two of the six patients to account for. They were both much relieved by the operation for a while; but after a few days they again fell off; and after many more days of gradual sinking and distress, they died. The cavity of the pleura contained, in both cases, much puriform liquid, and a quantity of most offensive gas, consisting in great part, as I judged from its odour, of sulphuretted hydrogen. I have since thought that both these patients would have had a much better chance for life, if this corrupt and corrupting mass had been duly removed.

Again, I have twice seen *pus* let out, by the *primary* puncture of the chest. One of these two patients sank, exhausted, some months after the opening, which never healed, was made. The empyema of the other had been occasioned by fracture of a rib. The discharge continued for a short time, then ceased, the orifice closed, and the lad got well.

This constitutes the amount, or nearly so, of my personal experience of the operation of paracentesis thoracis. You will see, in the statement I have been making, the grounds of those opinions which I have formed and expressed respecting it. A full and final solution of the grave and difficult questions that it involves would require a much wider field of observation than any one individual is likely to command. Dr. Thomas Davies has published a tabular account of the several cases of operation which he had then superintended. In sixteen cases of empyema, so treated, there were twelve recoveries; that is, the operation was successful in three-fourths of the whole number of cases: a very encouraging result. In three of the less fortunate cases, the lung could not expand after the evacuation of the fluid, in consequence of the thickness of the false membranes covering it.

The value of Dr. Davies' table would have been greater, if it had shown in each case the time, after the commencement of the disease, at which the operation was performed; the symptoms that called for its performance; the nature of the liquid evacuated; and whether the orifice made by the trocar was closed or not.

The quantity of liquid which the distended pleura is capable of holding is enor-

mous. I have seen upwards of a gallon let out at once. Dr. Townsend mentions the case of a patient of Dr. Croker's, in Dublin, from whose left pleura Mr. Crampton drew off the almost incredible quantity of fourteen imperial pints of pus. Of course this could not have accumulated there without making injurious pressure in all directions: upon the ribs, upon the heart and mediastinum, upon the diaphragm, and the abdominal viscera beneath it. It is interesting to know with what rapidity the capacity of the diseased side of the thorax may, in favourable cases, diminish. The same writer gives the history of a boy, twelve years old, in whom the circumference of the diseased side was sixteen inches and six lines, while that of the sound side was fourteen inches and one line. Nine days after the operation the circumference of the diseased side had decreased nearly three inches: it measured thirteen inches and nine lines; that is, rather less than the circumference of the healthy side. The side had shrunk somewhat within its natural size. This is common in such cases.

There is yet a third question of some importance. Whereabouts should the opening be made?

If any soft inelastic tumour have appeared, marking a tendency in the effused liquid to make its own way outwards, that tumour should be punctured without loss of time; for there will then be *no* chance of the reabsorption of the pus; and if the swelling be left to itself, troublesome, burrowing sinuses will be apt to form in the thoracic and abdominal parietes. As we have no choice in such a case about the place where the aperture is to be made, authors have termed the operation *the operation of necessity*; and they distinguish the case in which the surgeon is at liberty to introduce his trocar wherever he pleases; they say that then the *operation of election* takes place. Now the question is, what spot is the best for this operation of election?

If there be any part of the surface which is resonant on percussion, or which affords any sound of respiration, that part must be avoided. It is probable that the lung, in that place, is fastened by adhesions to the costal pleura. Of course you would not thrust in a trocar where you saw or felt that the heart was beating.

The object to be kept in view is that of making the opening in the situation which will allow the most free and perfect vent for the liquid. The intercostal space between the sixth and seventh true ribs, where the digitations of the serratus major meet those of the obliquus externus muscle, is the place usually recommended. Laennec prefers the space between the fifth and sixth ribs. He observes that, on the right side, an enlarged liver frequently reaches as high as the sixth, or even as the fifth rib. When the diaphragm is pushed as high as this (and I believe that Dr. Edwin Harrison, who had paid much attention to this point, could have told you that it is often pushed up even higher) there is an obvious risk of penetrating it with the trocar. In fact, Laennec committed that error himself. After making an incision between the fifth and sixth ribs, he thrust the instrument, as he supposed, into the thorax; and was a good deal surprised to find that no gush of liquid followed its introduction. The patient died; and dissection showed that the trocar had entered the cavity of the abdomen after transfixing the diaphragm, which, having been forced upwards by a large liver, had contracted firm adhesions to the seventh rib. I have myself witnessed a similar mischance, on the other side of the chest. The integuments of the side were œdematous; and it was thought that a little serum issued upon the passage of the grooved needle. The serum must have come from the infiltrated areolar tissue. No liquid was evacuated by the trocar. The patient died a day or two afterwards of peritonitis. The instrument had perforated the diaphragm, and entered the spleen, which was unusually large.

I am tempted to relate the particulars of one of the prosperous cases that I briefly adverted to before. It occurred in a lad of nineteen; a patient of my colleague's, Dr. Wilson. On his admission into the hospital he bore all the marks of copious effusion into the left pleura; the side enlarged, and motionless, and dull on percussion; the intercostal spaces tense, and level with the ribs; the heart beating to the right of the sternum; respiration puerile on the right side, inaudible on the left; urgent dyspnoea; a tendency to coma, marked by drowsiness and blueness of the cheeks and lips. In short, the boy was on the very verge of suffocation. He had been ill about a month; and had been bled, and cupped, and brought under the specific influence of mercury. Dr. Wilson judiciously directed that the liquid should be let out.

A grooved needle was first passed between the fifth and sixth ribs; and some serum

following the puncture, a trocar was then introduced by Mr. Tuson, and nine pints of a clear fluid were drawn off. During the operation the patient became faintish at times, and then the orifice of the canula was stopped for a moment by the finger. The immediate effect of the tapping was most interesting and gratifying. Even while the liquid was flowing, the heart was observed gradually to move over from beneath the right mamma towards its natural situation; and his difficulty of breathing was signally relieved. At the beginning of the operation he respired fifty times in a minute; at its conclusion thirty-eight times only. A good deal of air entered while the liquid was escaping: and for some days after the operation a splashing sound was audible on succession of the chest; and one part of that side was unnaturally resonant, when struck, and another part unnaturally dull; and whatever was the posture of the patient, the hollow sound was uppermost, and the dull sound undermost; and when he sat up and spoke, or coughed, a brazen resonance was heard by the ear applied to the scapular region. This had got quite well, without the recurrence of a single bad symptom. He afterwards presented himself at the hospital; and I understand that the left side was found to be in a very slight degree smaller than the right.

The liquid evacuated in this case was clear and transparent. It separated, on cooling, into three parts; one of quite watery consistence, one more viscid, and a third which constituted a soft, transparent, jelly-like mass of fibrin.

In this instance no injurious consequences resulted from the free admission of air.

It may sometimes be necessary to puncture the cavity for *mere* pneumothorax: when, for instance, the pulmonary pleura has been pricked by a fractured rib, and air passes from the lung into the pleural sac faster than it can be absorbed; fast enough to compress the lung, and to threaten death by apnoea. The diagnosis of such a state cannot be difficult. The existence of the fracture, the tympanitic sound yielded by the chest on the injured side, the absence of respiratory murmur in the tympanitic part, and the increasing dyspnoea, all point to the same conclusion. Now a trocar of the smallest size—or even an aepuncture needle—may suffice to give vent to the imprisoned air, which will escape with an audible hissing noise. In some cases it must have existed in very large quantity, for the stream of issuing air has been strong enough to blow out a candle several times in succession; the flame being each time immediately re-lighted.

The same necessity for puncturing the cavity of the pleura from without may arise in cases of pneumothorax depending on specific disease in the lungs; but we cannot regard the operation as *curative* in such cases. Its value is very different from that which experience has shown to belong to it in empyema from acute or chronic (but simple) pleurisy. Yet if it save life for the time, if it prevent impending suffocation, and relieve existing distress, and postpone the fatal event, it is not *without* its value: and it has many times been done, and been followed by very gratifying results; but it has never, that I know of, been followed by entire recovery. Dr. Davies had superintended the operation in nine instances of pneumothorax with effusion; and *all* the patients died from tubercular complications.

There are, indeed, on record, examples of recovery after the operation, when pneumothorax had existed, and under very unpromising circumstances. I should have stated before, that as the pus, in empyema, sometimes finds its way outwardly, penetrating between the ribs, and forming an external swelling, which, if not opened by the scalpel, will at length burst; so it also, sometimes, escapes by making a road into some part of the air-passages, and being expectorated. Now the operation of paracentesis, in such a case, *there being no tubercular disease*, has been successful. Le Dran relates an instance in which he operated for empyema, where “the injection of a small quantity of mel rosarum and barley-water through the wound excited coughing, and part of it was coughed up through the mouth, mixed with pus;” thus clearly proving the existence of a fistulous passage through the lung; notwithstanding which the patient recovered completely. The effusion was probably circumseribed. But you will find other cases of a similar kind referred to by Dr. Townsend, in the *Cyclopædia of Practical Medicine*: and I may briefly mention one which has fallen within my own experience.

A gentleman, twenty-two years of age, had the ordinary symptoms of pleuritic inflammation. There had been no previous evidence of pulmonary disease. After a while he began to expectorate pus of a very offensive odour. The physicians in

attendance upon him came to the conclusion that a circumscribed collection of pus in the pleural cavity had found its way, by ulceration, into the air-passages. The patient was gradually wasting away. Auscultation long failed to disclose the exact seat of the presumed collection of matter. At length, in a small spot between the scapula and the spine, on the affected side, the mingling of air with a liquid was heard during inspiration. As under the existing circumstances life seemed drawing inevitably towards its close, it was determined, in a consultation at which I was asked to assist, that an attempt should be made to let the matter out by puncturing the chest. The place at which the operation was of necessity performed rendered it a difficult one; but Mr. Stanley succeeded in reaching the abscess, and in evacuating nearly two pints of pus. The wound was kept open. From that time the offensive expectoration by the mouth ceased. Gradually the discharge from the back became less, until there was none. The opening healed in three months after the operation, which was performed in May, 1850, seven years ago. The patient recovered perfectly, and is now a healthy man.

Since these lectures were last submitted to the press, I have witnessed several other cases in which paracentesis thoracis was deemed advisable. The subject has also been expressly treated of by Dr. Hughes and by Dr. Hamilton Roe. To those gentlemen the profession is much indebted for having shown with what facility, and with how little risk and pain, the operation may be performed. They have not convinced me of its frequent necessity. In so far as simple pleurisy and its consequences are concerned, my own opinion, after careful reconsideration, remains unchanged. The operation seems more extensively applicable, however, than I had formerly supposed, to other cases, where its object and effect are to alleviate present suffering, and to prolong life which it is unequal to save: cases of pneumothorax, and of serous or puriform effusion connected with malignant or tubercular disease of the lungs. But in mere pleuritic effusion I would not puncture the chest, however devoid of hazard that procedure may be, unless I knew that the contained fluid was pus, or unless there was no prospect of recovery without it. I except here the minor diagnostic puncture with the grooved needle. In one very interesting case, related by Dr. Hughes in the 8th volume of the *Guy's Hospital Reports*, the pneumothorax ceased after—it may be fairly said was cured by—the second evacuation of the affected pleura by tapping the chest. The air must have escaped from a small cavity in the lung, which afterwards rose and became adherent to the costal pleura. The patient died from rapid tubercular disease of the other (the left) lung. The right being removed, and submerged in water, not a bubble of air could be made to escape from it by inflation. Air had been absent from the pleural cavity from July 24th to May the 22d of the following year.

This concludes what I have to say, not only of pleurisy, but also of pneumothorax, and of empyema, which are often treated of as separate and independent disorders. They are more frequently connected with pleurisy than with any other form of disease, and they are almost always *consequences* of disease or of injury. But I believe I have omitted nothing of importance in respect to either of them.

LECTURE LIV.

Pulmonary Hæmorrhage: its varieties; its connexion with pulmonary consumption, and with disease of the heart. Pulmonary Apoplexy. Prognosis in Hæmoptysis. Symptoms. Treatment.

HAVING gone over the *inflammatory* affections of the organ of respiration; having brought before you inflammation of the membrane which *lines the air-passages*, or *bronchitis*; inflammation of the membrane which *invests the lungs*, or *pleurisy*; and inflammation of the *whole substance* of those organs, or *pneumonia*; I proceed next to the subject of *pulmonary hæmorrhage*.

You may remember that, in an early part of the course, I drew your attention to some general facts respecting internal hæmorrhages. I showed you that the blood does sometimes proceed from a ruptured vein or artery, but that it is much oftener poured forth through unbroken surfaces, from a multitude of capillary vessels; and that hæmorrhage of this kind takes place from the *mucous membranes* far more frequently than from any other natural surface of the body. I observed also that such hæmorrhage is almost always preceded by congestion; either by active congestion, which is less common, or by passive and mechanical, which is extremely common: and we speak, accordingly, of active and passive hæmorrhage. Hæmorrhage is also sometimes primary, or idiopathic, and then constitutes the whole disease; while at other times it is merely a symptom, direct or indirect, of some other disorder, in which case we call it secondary.

Now in the lungs we find examples of all these varieties of internal bleeding; but pulmonary hæmorrhage is secondary much more often than it is primary.

In speaking, therefore, of some forms of pulmonary hæmorrhage, I must touch upon certain diseases of which the bleeding is a symptom: but I shall not go further into the consideration of those diseases at present, than may be necessary to elucidate the hæmorrhage. Bleeding from the lungs is a thing of most fearful interest; and it will be useful to take a general view of that phenomenon, whether it be a substantial disease in itself, or merely a sign of other pre-existing diseases.

The blood, then, in pulmonary, as in all other hæmorrhages, may issue through a breach in the walls of some considerable blood-vessel; or it may proceed from innumerable capillaries distributed to the mucous membrane of the lungs: and the latter mode of hæmorrhage is much the more common of the two, although it is the popular belief that the "breaking a blood-vessel in the lungs" is of very frequent occurrence.

The particular vessels injured in the first class of cases, and the nature and origin of the breach made in their sides, are matters of infinite variety. Sometimes the blood is extravasated through apertures, the results of a disorganizing process which has commenced in the coats of the vessels themselves; as when, for example, aneurisms of the thoracic aorta, or of its primary divisions, burst, and pour their contents into the air-tubes. Having pointed out this accidental and well-nigh hopeless form of pulmonary hæmorrhage, I shall postpone any further account of the disease that gives rise to it, to a future lecture.

Sometimes, again, a large blood-vessel is laid open by the encroachment and extension of disease from contiguous structures. Here is represented (Carswell, fasc. vi. plate iii. fig. 5) the perforation of a large branch of the pulmonary artery, and of a neighbouring bronchial tube, by the extension of tubercular ulceration. The blood escaped so abundantly in this case, that the patient was dead in less than a quarter of an hour. And here I show you a preserved specimen of a similar opening made in the pulmonary vein.

It will be necessary that I should anticipate somewhat; and in order to include in one view all that relates to pulmonary hæmorrhage, that I should speak cursorily of its connexion with tubercular phthisis. No one here can be ignorant that in that terrible disease portions of the lung are liable to be hollowed out by the softening and expulsion of tubercular matter, into what are called *vomicæ*. Now seeing that

hæmoptysis occurs very frequently in persons labouring under consumption, and that the expectoration of blood is often copious, and takes place when it is evident that there are tubercular excavations in the lung, it would be very natural for you to suppose that the bleeding in such cases proceeded from large vessels which had been laid open during the softening of the tubercles, or by the subsequent extension of the ulcerating cavities. But in point of fact, this is very *rarely* the case. I shall explain to you hereafter how it happens that this hæmorrhage from the larger vessels is *generally* prevented; still it does *sometimes* happen.

But in a far greater number of instances the blood in hæmoptysis is *poured forth* from the mucous membrane that lines the air-passages. When this surface is examined in the dead body, and immediately after the occurrence of pulmonary hæmorrhage, it is very often found to be perfectly entire, from the commencement of the trachea to the remotest divisions of the bronchial tubes; as far, at least, as minute dissection can follow them. The membrane in these cases is usually red, as in simple bronchitis; but it is sometimes pale, or shows scarcely any traces of vascularity. The former of these appearances results from the continued turgescence of the submucous capillary vessels; the latter is the consequence of their having been completely emptied of blood by the last hæmorrhage. We shall meet with analogous conditions when we come to examine the hæmorrhages that proceed from *other* mucous surfaces; and especially from that of the alimentary canal.

When blood is thus discharged from the mucous membrane of the air-passages, the hæmorrhage may be strictly primary or idiopathic; *i. e.*, it may be independent of any discoverable alteration of texture, either in the mucous surface itself, or in any other part which, by reason of some intelligible connexion of structure or relation, seems capable of influencing the capillary circulation of the membrane. But the occurrence of pulmonary hæmorrhage strictly idiopathic has been more frequently affirmed than proved. Active hæmorrhage from the lungs is stated by systematic writers to be the hæmorrhage of adolescence, as epistaxis is that of childhood. I believe, however, that idiopathic active hæmorrhage from these organs is very rare indeed; unless we may consider as such, certain forms of *vicarious* bleeding, which I shall presently advert to. Andral tells us that in one instance only, in which hæmorrhage from the surface of the air-passages had been the immediate and apparently the sole cause of death, had he ever found the substance of the lungs free from *tubercles*, and perfectly *healthy*. He does not, however, state whether in this one instance the *heart* also was in its natural condition: an important omission, as we shall hereafter perceive. He relates, indeed, as an example of idiopathic hæmoptysis, the case of a young man who suffered profuse hæmorrhage from the lungs on four several occasions, between the ages of twelve and eighteen, without any apparent detriment to his health, which remained excellent. It is consistent, however, with much experience to suppose that crude tubercles might have been scattered through the lungs of this person, and have sufficed, on the application of some exciting cause, to determine the hæmorrhage, although as yet their presence was not indicated by any other sign. Almost every systematic writer quotes, as an example of idiopathic hæmorrhage from the lungs, the story of the Roman governor, mentioned by Pliny, who lived to the age of ninety, though he was afflicted with habitual hæmoptysis. Now the frequent citation of this supposed instance is of itself a sufficient proof that spontaneous pulmonary hæmorrhage is far from being common.

Cæteris paribus, the *disposition* to pulmonary hæmorrhage is increased by whatever tends to diminish the capacity of the thorax, and to compress the lungs, or the heart and great blood-vessels. The mechanical congestion thus produced may become a very intelligible cause of the exudation of blood from the mucous membrane. And it is partly on this principle that we may account for the frequency of hæmoptysis in persons with crooked spines; in tailors, who sit continually in a stooping posture; in young women who lace their stays too tightly; and even in those who labour under dropsy, or other cause of distension of the belly. Hæmoptysis accompanying ascites has been known to cease at once upon the performance of the operation of tapping, and to recur upon the reaccumulation of the dropsical fluid; and this not on one occasion only, but so often and regularly as to preclude all notion of accidental coincidence. There can be little doubt, however, that in this class of cases, or at least in a vast majority of them, the hæmoptysis is mainly to be ascribed to organic disease

of the heart or of the lungs; and that the pressure which precedes and determines the bleeding is simply a *concurrent* cause.

If we cannot properly rank *that* pulmonary hæmorrhage as idiopathic, which is constitutional and vicarious of some other natural or morbid discharge, — and most frequently of all of the menstrual discharge in females, — it may be considered as forming a link of connexion; as lying midway between secondary and primary hæmorrhages. There are a great number of very curious and well-authenticated facts upon record concerning this singular form of hæmorrhage by deviation. I will give you one history of the kind by way of sample; it is related by Pinel, who held that there was no supplemental hæmorrhage more common than the hæmoptysis that is vicarious of menstruation.

A female, 58 years old, born of healthy and robust parents, of strong constitution, of a sanguine and plethoric temperament, and of great sensibility, lived in the Salpêtrière, and was therefore under constant observation, from the age of 14. She enjoyed excellent health till she was 16 years old. In her 16th year the menstrual discharge commenced without mishap or difficulty; but this, her *first* menstruation, was suddenly suppressed, in consequence of the fright and agitation produced by the sight of an epileptic patient in strong convulsions. From that time the catamenia *never* reappeared, nor did any kind of discharge take place from the genital organs; but at the next period, when regular menstruation ought again to have come on, the girl was attacked with violent hæmoptysis. The hæmorrhage was preceded by vague pains, in the uterus and loins, and by other symptoms which frequently announce the catamenia. It lasted two days, during which time the girl expectorated nearly a quart of blood. With one interval only of exception, this female continued to menstruate *through her lungs* at each monthly period, from her 16th to her 58th year, *i. e.*, during 42 years of her life. The coming on of the hæmorrhage was sometimes a little accelerated by strong mental excitement; sometimes a little retarded by causes of a contrary nature. It was suspended during one whole year, without any serious impairment of the general health, or the occurrence of any other hæmorrhage: during this interval, however, the patient suffered most severe headaches. Occasionally the hæmoptysis was complicated with hæmatemesis. The symptoms by which the pulmonary hæmorrhage in this instance was generally preceded or accompanied were the following: — a sensation of weight and uneasiness in the loins and in the situation of the uterus, soon followed by chilliness of the surface, general lassitude, and a feeling of oppression and heat in the chest, with some dyspnoea. The face became red, and she had intense headache. Then she began to have a distinct sensation of pricking, and of a sort of bubbling, in the trachea and about the commencement of the bronchi; then followed sharp cough, and the expectoration of blood, often bright coloured and frothy, sometimes of a darker hue. The duration of the hæmoptysis was generally confined to a single day, and it never exceeded three days. It recurred with tolerable exactness at monthly periods; sometimes the interval was longer, and then the *hæmorrhage* continued longer, but was less abundant; and upon the whole, about the same quantity of blood was lost on each occasion. This woman continued plump, and otherwise healthy, though liable to some thickness of the breath upon unusual exertion.

Cases of this kind are not at all uncommon; although the vicarious hæmorrhage seldom persists so long and so steadily. They are not usually attended with any peril to life.

It is, however, a melancholy truth, that capillary hæmorrhage from the mucous membrane of the air-passages, is dependent, in a very large proportion of instances, upon incurable disease. The hæmorrhage is secondary; and the disease of which it is symptomatic is usually a fatal disease. And the complaint, of which hæmoptysis is by far the *most frequently* symptomatic, is tubercular phthisis. When the tubercles are found upon dissection to be yet crude and entire, and no breach can be detected in the membrane, then no doubt can be entertained about the source and manner of the bleeding; and even when cavities exist, especially if they are found to contain no blood, it is probable that, in most cases, the hæmorrhage has had a similar origin.

When hæmoptysis is thus actually symptomatic of tubercular disease of the lungs, it is liable to considerable variety in regard to the period of its first occurrence, and the symptoms by which it is succeeded. There are many persons in whom the *first*

attack of hæmoptysis precedes, even for years, the primary symptoms of unequivocal phthisis. There are others in whom the first attack of hæmoptysis is *immediately* followed by all the signs, which announce the presence of tubercles in the lungs. Many, again, do not spit blood until the tubercles have acquired a considerable degree of development, and the phthisical symptoms have been for some time clearly marked; and occasionally, in these cases, the first hæmorrhage proves fatal. Lastly, it is far from being an uncommon thing to see pulmonary consumption run its whole course, and terminate in death, without having been attended with *any* spitting of blood.

Andral gives the following statement as the result of his own observation, in regard to the relative frequency of these several modes of connexion between hæmoptysis and consumption.

Of the persons whom he had known to die of that disease, one in six never spat blood at all. Three in six (or one-half of the whole number) did not spit blood until the existence of tubercles in the lungs was already made certain by unequivocal symptoms. In the remaining two-sixths the hæmoptysis preceded the other symptoms of tubercular disease, and *seemed* to mark the period of its commencement.

By this comparative statement you will see how very frequently hæmoptysis occurs as one of the symptoms *connected* with tubercular phthisis. Under this physician's observation it happened in five cases out of six. In the experience, however, of M. Louis, the proportion, though very large, is not quite so great as Andral found it. Among eighty-seven instances of consumption, there were fifty-seven, or four in every six, in which hæmoptysis had been present.

It has, however, been made a question, whether the spitting of blood which thus occurs in *connexion* with tubercular phthisis, is always to be considered as indicative of the *existence* already of tubercles in the lungs; or whether it may not sometimes precede, and give occasion to, their formation in those organs. This question has evidently been suggested by those cases (constituting, according to Andral, one third of all that happen) in which the ordinary signs of phthisis *begin* to manifest themselves immediately upon the occurrence of the first hæmoptysis, or within a short time afterwards. Morton, who has noticed this kind of pulmonary hæmorrhage, includes among his *species* of phthisis, the "phthisis ab hæmoptœ;" and Cullen held that *spitting of blood* was often the *cause* of pulmonary consumption. It is a very important question, and I shall revert to it again hereafter.

Next to *tubercular* disorganization of the *lungs*, the most frequent source of pulmonary hæmorrhage is to be found in organic diseases of the *heart*. It has been stated by Chomel, Bouillaud, and others, both in this country and abroad, that the disease in these cases is most commonly situated in the *right chambers* of the heart. But certainly this is a mistake. The error has arisen from arguing upon erroneous analogies, instead of attending to matters of fact. However, the statement is just as little supported by reason as it is by the result of general experience. The only alteration in the right cavities of the heart which we could suppose likely *à priori* to cause pulmonary congestion, and thereby hæmoptysis, would be increased strength and thickness of their muscular parietes: hypertrophy: a morbid condition which is comparatively rare on that side of the heart, and which, perhaps, would not suffice for the production of hæmoptysis, even if it did oftener exist. The direct effect, on the other hand, of any *obstacle* to the free passage of the blood in the right chambers of the heart, would be to gorge the *liver*, and the system of the *vena portæ*; and to prevent the lungs from receiving their due proportion of blood. But any material obstruction existing in the *left auricle* or *ventricle* will impede the return of blood *from* the lungs, lead to its accumulation in those organs, give rise to mechanical congestion, and so dispose strongly to pulmonary hæmorrhage. And, in point of fact, we find that hæmoptysis is very frequently the result of disease in the left side of the heart; and this leads me to speak here of one very remarkable morbid condition of the lungs, which is often directly connected both with pulmonary hæmorrhage and with cardiac disease; though it is not *always*, or *necessarily*, associated with either.

The morbid state to which I allude is far from being infrequent; yet it had been scarcely noticed by or known to pathologists, until Laennec described it under the title of *pulmonary apoplexy*. It appears under two forms. In the one form we find

an uncertain number of hard knobs, or compact masses, situated here and there in the substance of the lungs, chiefly in their lower lobes, and towards their posterior surface. Their size varies from that of a marble to that of a hen's egg. When cut through they are seen to be very exactly circumscribed, the cut surface being more or less circular, of a uniform and very dark colour throughout, and exhibiting a strong contrast with the surrounding tissue. Careful examination shows that these masses are composed of blood that has coagulated in the pulmonary vesicles. *Occasionally* the pulmonary substance seems broken down, or torn, by the extravasated blood; and in these cases, perhaps, the resemblance between the injury done to the lung, and that which is inflicted on the substance

FIG. 58.

Pulmonary apoplexy, occurring in a man aged 53. There were several apoplectic masses, exhibiting a deep purple, almost black hue, and causing an homogeneous solid appearance of the part affected, as shown in the section.

of the brain in *cerebral* hæmorrhage, is tolerably close. Generally, however, there is no such laceration of the pulmonary tissues; but one, or more, of the *lobules* of the lungs, are gorged and crammed with blood, which has been poured out from the surface of the mucous membrane. These lobules, it is well known, have no direct communication with each other; but are isolated (except where they severally open into the bronchial tubes from which they spring) by a distinct investment of areolar tissue; and it is to this peculiarity in *their* structure and disposition, that the exact circumscription of the dark-red indurated masses is to be attributed.

In the other form of pulmonary apoplexy, there are fewer of these solid spots; perhaps one only, large, diffused, occupying sometimes nearly the whole of one lobe, its limits obscurely defined, and its colour gradually deepening to the centre, which is obviously formed by little else than a black clot of blood.

Now the principal *symptom* attending the formation of these masses is *hæmoptysis*; and the principal though not the only *cause* is disease of the heart. The hæmorrhage is often severe and copious in the first or circumscribed form: sometimes slight and scanty, but commonly slow, oozing, and persistent, in the second or uncircumscribed form. The heart-disease is in its left chambers, and very often consists in contraction of the mitral orifice. No example of pulmonary apoplexy, or of pulmonary hæmorrhage, even *apparently* dependent upon hypertrophy of the *right* side of the heart, has ever fallen under my notice.

In truth that morbid condition of the lung which I am now speaking of, has been badly named. The application, by Laennec, of the term *apoplexy* to the *lungs* was singularly unfortunate: for it suggests an analogy between two things, which, though resembling each other in the appearances which they leave behind them in the organ affected, are yet, essentially, unlike. I have shown you, in a previous part of the course, that cerebral hæmorrhage depends almost always upon the giving way of a blood-vessel, in consequence of the morbid brittleness of its coats: while what is called pulmonary apoplexy can very seldom be so caused. The notions which I have been led to form upon this subject differ materially from those which you will find expressed in the works of almost every writer on pulmonary apoplexy. The opinions I entertain were stated several years ago, in some lectures which I was appointed to deliver before the College of Physicians; and I have constantly been in the habit of mentioning them to the pupils at the Middlesex Hospital, and to my medical friends. It is a matter of satisfaction to me to find that they are esteemed to be correct by so sound a pathologist as Sir Robert Carswell, who has alluded to them in one of his fasciculi on the *Elementary Forms of Disease*. Laennec speaks of the pulmonary apoplexy, as if it were the *cause* of the hæmoptysis. But this is surely a very incorrect view of the matter. The partial engorgement, and the hæmoptysis, are not mu-

tually connected with each other as cause and effect, but they are *concurrent* effects of the *same* cause; of that cause which gives rise to the extravasation of the blood in the first instance. A part of the blood so extravasated passes outwards by the trachea and mouth; while a part is forced in the contrary direction, into the ultimate divisions of the bronchi, so as to fill and block up the whole tissue of a single lobule, or of a bunch of contiguous lobules, and thus arises the *circumscribed* variety. Andral conceives that the sanguine effusion *takes place* in the ultimate air-cells; and he applies to this form of disease the term *pneumo-hæmorrhage*, to distinguish it from ordinary hæmoptysis, which he calls *bruncho-hæmorrhage*; and this I believe to be the true pathology of the *uncircumscribed* variety. But it seems to me vastly more probable that in the other form of the complaint the seat of the effusion is in one or more of the larger branches of the air-tubes; and that the blood, a part of it at least, is driven backwards into certain of the pulmonary lobules, by the convulsive efforts to respire which the patient makes, when threatened with suffocation by the copious expulsion of blood, or by a paroxysm of cough and extreme dyspnoea; especially if the blood be poured out from the membrane while the chest is in the state of *expiration*. It is easy to understand how certain portions of the lungs, without undergoing any actual change of texture, may in this manner be so choked up, and crammed with blood, which afterwards coagulates, as to preclude any subsequent admission of *air*.

This view of the formation of circumscribed pulmonary apoplexy, affords an easy explanation of some of the phenomena attending it, which it would be difficult to account for on any other supposition. I mean, first, the occurrence of *several* of the clots, or masses of blood, in different, and sometimes in distant, parts of the lung at the same time; and secondly, the exact manner in which they are commonly bounded and limited to certain lobules. And if (as is sometimes, though seldom, the case) even the texture of the lung be lacerated, it is easier to conceive that this may happen in consequence of the violence of regurgitation during the struggle of impending suffocation, than that the mere impulsion of a thickened mucus at the centre of the circulation should be capable of driving the blood through the walls of an artery with sufficient force, to tear and break down the substance of the lung around it.

In the diffused or uncircumscribed form of pulmonary apoplexy, the congested lung is not relieved by a sudden and copious gush of hæmorrhage, but the impeded and stagnating blood oozes slowly from the vessels containing it into the neighbouring interstitial and vesicular tissues, clogs up a larger and larger space, and is partly expectorated in separate dark-red sputa, combined with a certain quantity of mucus. A similar condition of the lung sometimes occurs in *purpura hæmorrhagica*, without any mechanical impediment to the passage of the blood into and through the heart.

The belief that the dark-coloured, circumscribed spots seen in the lungs, and spoken of as pulmonary apoplexy, are often, if not always, produced in the manner I have just been describing, was suggested to me by the observation of a case, in which these appearances existed, and in which they *certainly were* so occasioned. I told you, when speaking of cynanche tonsillaris, that I had seen one person, and one only, die in consequence of that complaint; and that his death was occasioned by the laying open of the lingual branch of the carotid artery in the progress of ulceration. The phenomena attending the patient's dissolution were of deep, though of painful interest. I described them to you before. He had been taken out of bed, and laid upon a table in the ward, in the middle of the night, in order that Mr. Mayo might more conveniently place a ligature upon the carotid. Suddenly the bleeding burst forth afresh: and he expired, before our eyes, in the course of two minutes: not from syncope or exhaustion, but evidently suffocated. The blood entered and choked up the trachea, and he had not strength enough left to expel it by coughing. I felt his heart and the artery at his wrist pulsate firmly for some little time after the last attempt to dilate the chest had been made. This you know is what always happens when death takes place from the sudden denial of air to the lungs. We found the upper surface of the glottis covered by a clot of blood. There was blood also *in* the windpipe; and scattered through the substance of the lungs there were numerous hard, and dark, but not very large masses, precisely resembling those described by Laennec as constituting pulmonary apoplexy. This man had shown no symptoms of any pulmonary complaint; nor was there any morbid appearance in his lungs except

those which resulted from the presence of the blood that had been poured into them through the trachea, and rammed home into some of the air-cells, in his convulsive attempts to breathe. All that I have observed since this case happened, has tended to confirm my belief, that what has been erected into a distinct form of disease, under the objectionable name of *pulmonary apoplexy*, is simply an *accident of pulmonary hæmorrhage*. When hæmoptysis has occurred, to any amount, in *consumption*, it is by no means uncommon to find pulmonary apoplexy after death; and Dr. Latham has mentioned to me, in conversation, one remarkable instance of that disease, strongly corroborative of the doctrine I have been endeavouring to support. A young female patient of his, labouring under confirmed phthisis, was attacked, for the first time, with hæmoptysis. The bleeding was so profuse as to cause almost immediate death by suffocation. Her lungs were found riddled with small tubercular cavities; and each of these little cavities contained a little clot of blood. Surely it is more credible that the blood should have reached each cavity by regurgitation from the larger air-tubes, than that each should have been the seat of an independent hæmorrhage at the same moment. It is by a similar reflux of blood that the appearances are produced which characterize the circumscribed form of pulmonary apoplexy.

Upon the whole, the occurrence of hæmoptysis, considered in reference to the probable duration of life in those who are the subjects of it, is of melancholy omen.

I have long arrived at this conclusion:—that if from any given number of persons who have been known to spit blood, we subtract those in whom that symptom was connected with irregularity in the uterine functions, there will remain but few in whom the hæmoptysis did not depend upon disease, incurable and progressive in its nature, of the lungs, or of the heart; and that if we still further subtract those persons in whom the hæmorrhage was symptomatic of cardiac disease, there will be very few indeed left, in whose lungs the existence of tubercles may not be confidently predicated.

Among these few may be reckoned persons who have suffered hæmoptysis dependent upon the detachment and expulsion of “bronchial polypi;” and who exhibit no other indication of cardiac or of pulmonary disease.

You will, of course, understand that I do not include in this estimate of hæmoptysis as a prognostic symptom, those cases in which (as in simple bronchitis) the expectoration is merely *streaked* with blood:—nor those in which small quantities of blood are intimately combined and amalgamated with the bronchial mucus, and form the rust-coloured sputa so indicative of the presence of pneumonia:—nor those in which the hæmorrhage is a consequence of mechanical injury to the chest.

Of those individuals whom Andral had known to spit blood at some period or other of their lives, there was only one in five whom he did not also *know* to have tubercular phthisis. On the other hand, Louis states that for upwards of fifteen years he asked all the patients who came before him, in the practice of a large hospital, and who were *not* affected with phthisis, whether they had ever spat blood; and the answer was always in the negative, excepting only a few instances in which the patients had received violent blows upon the thorax; and the cases of females in whom the menstrual discharge had been suddenly suppressed.

The quantity of blood which is brought up in different cases of pulmonary hæmorrhage, is extremely variable. Sometimes it is so copious and overwhelming that either the patient dies suffocated, or he dies of syncope, outright; but this is not very common. Sometimes, on the other hand, a small quantity of blood finds its way into the mouth, the patient scarcely knows how. And between these two extremes there is every gradation in respect of quantity.

“When blood is thrown out by the mouth (says Cullen), it is not always easy to determine from what internal part it proceeds; whether from the internal surface of the mouth itself, from the fauces, or adjoining cavities of the nose, from the stomach, or from the lungs. It is, however, very necessary to distinguish the different cases.”

Now the diagnosis between hæmorrhage from the lungs and hæmorrhage from the stomach, in other words, between *hæmoptysis* and *hæmatemesis*, I shall not enter upon, until I have described the latter disease. And the diagnosis between hæmorrhage from the fauces or cavity of the mouth, and hæmorrhage from the lungs, can never be very difficult, if once the doubt suggest itself, and the necessary examination

of the mouth be made. And I would advise you not to omit that inspection. I could tell you of cases in which the neglect of this simple precaution has led to needless activity of treatment, and to the ultimate discredit and disadvantage of the practitioner. Blood may ooze into the mouth from spongy gums, or drip from the posterior nasal orifices, and be at length spat out in considerable quantity. Etymologically speaking, these are cases of *hæmoptysis*; but they do not constitute the particular disease or symptom to which alone nosologists have agreed to restrict that term. The sources of the bleeding are manifest as soon as they are carefully looked for.

Patients who are subject to hæmoptysis generally know by experience when it is about to happen. It is frequently preceded by some uneasy feeling within the thorax — pain, or a sense of weight, or of heat, or of pricking, beneath the sternum, with anxiety; and they tell you that they taste the blood in their mouths before it comes up, *i. e.* they perceive a saltish taste; and just before the blood appears, a tickling sensation is experienced about the top of the larynx. To relieve this sensation, the patient coughs or hawks a little, and a certain quantity of frothy and florid blood is expectorated.

In a person disposed to pulmonary hæmorrhage, the bleeding may be determined by a variety of causes; which ought to be pointed out to him, in order that he may avoid them. Anything which hurries the circulation will, of course, have a tendency to excite the hæmorrhage. Straining of any kind; great efforts of the body; active exercise; much talking; and more especially public speaking, or singing, or playing on wind instruments. A diminution in the superincumbent weight of the atmosphere is supposed to be, in some cases, sufficient to bring on hæmoptysis; and blood is said to have been forced even from sound lungs, in persons who have ascended very high mountains, where the atmosphere is rare, and where the pressure upon the surface of the body is sensibly lessened. Perhaps the labour of the ascent may have shared in the production of the hæmorrhage; for I am not aware that any such effect has ever occurred to persons who have much more rapidly reached a very great altitude in balloons.

Auscultation and percussion do not stand us in much stead in cases of hæmoptysis, so far as that *symptom itself* is concerned. Indeed, if they were capable of affording us information, it would in most cases be superfluous; for we see the blood, and we can generally satisfy ourselves that it comes from the *lungs*.

But pulmonary hæmorrhage may occur without hæmoptysis. In what is called pulmonary apoplexy there is extravasation of blood: and it is not always attended with the expulsion of a portion of the extravasated fluid through the mouth. Laennec and others pretend to say, that when there is blood in the bronchi, they can distinguish, by the peculiar character of the crepitation to which it gives rise, that it is blood, and not mucus; that the bubbles, passing through a thinner liquid, are larger, and break oftener, than those produced by the passage of air through viscid mucus. This distinction is too subtle for me. If, indeed, there have been hæmoptysis, and especially if the hæmoptysis have been sudden and copious, and if, after it, you hear large crepitation in one or more isolated parts of the lung, it will be reasonable to conclude that the air-tubes contain blood in those parts. Those lobules that are plugged up with blood, to the entire exclusion of air, will not, of course, be the seat of any sound during respiration; but this limited absence of sound will be scarcely appreciable unless the infarcted portion lies near the surface of the lung. Around the spot thus rendered solid the sound of crepitation may be audible.

Yet, although the method of auscultation furnishes but little help towards the detection of pulmonary hæmorrhage, it will often afford us most precise and valuable information respecting the disease of which the hæmorrhage is a consequence, and an index. Thus, it will frequently teach us, with absolute certainty, that the heart is diseased, or that the lungs are occupied by tubercles. The precise sounds, or deficiencies of sound, which supply the key to this knowledge, I shall describe when I come to those disorders.

Whatever may be the source and organic cause of the hæmoptysis, the bleeding should be stopped as soon as possible; not, however, merely by *suppressing* it, but by relieving the necessity on which it depends. The longer it is suffered to continue, the more likely is it to add to the damage, which already, in too many cases, exists in the lungs. If it lead to the formation of blocks of pulmonary apoplexy, the portions

of lung so filled up, are rendered useless for a long period, and probably for ever. Now as in most cases the hæmorrhage is a capillary hæmorrhage, and depends upon congestion, active or mechanical, we shall stay the hæmorrhage if we remove the congestion.

The congestion may be either mechanical, or active, when it results from the presence of tubercles in the lungs; it is almost always mechanical when it depends upon disease of the heart. The tubercles may press upon the blood-vessels and so lead to mechanical engorgement; or they may provoke by their presence an active determination of blood to those organs, just as we know that they often provoke inflammation, which is congestion and something more; and just as any foreign body lodged in the lung may cause either the one or the other of these conditions.

Frequently there is a distinct febrile movement accompanying the hæmorrhage: the heart beats with increased force and frequency, the cheeks are flushed, and the skin is hot; sometimes the pulse is quite hard, and full, and bounding, and people speak of such a pulse as a *hæmorrhagic* pulse. Now I mentioned in a former part of the course, that hæmorrhage occurring under such circumstances as these often works its own cure; but it is better, when an organ so vital and important as the lung is the seat of the effusion of blood, that we should cure the bleeding than that it should cure itself—that we should diminish the congestion with which it is linked, through the safer channels afforded by the veins of the arm, or by the capillary blood-vessels of the exterior of the chest. The patient is to be surrounded with cool fresh air. His head and shoulders should be elevated. He should be restricted to the most meagre diet; and be forbidden to exert himself, or to speak more than is absolutely necessary. His bowels should be freely purged, in the first instance, and then kept lax and open, both with the view of deriving (as it is called) from the thorax, and of preventing costiveness and straining. And, in conjunction with these measures, it may be requisite that he should lose blood from the arm, or from the surface of the thorax. The amount and the repetition of the bleeding must be determined by the circumstances of the case, *i. e.* by the cessation or continuance of the hæmorrhage, and especially by the condition of the *pulse*. It would be idle to attempt to lay down precise rules on this matter. We do not bleed, however, so resolutely and perseveringly in hæmoptysis as we are often obliged to do in acute inflammation.

A prejudice has been taken (such, at least, I deem it) against *local blood-letting* in pulmonary hæmorrhage. Inasmuch as leeches applied to the groins in amenorrhœa appear sometimes to restore the catamenia, so they have been thought likely, when applied over the surface of the chest, to attract the blood somehow to that part of the body, and even to *cause* hæmorrhage when none before existed. Now I have so many times taken blood from some part or other of the exterior of the thorax by leeches, or by cupping-glasses, without observing any such effect, of causing hæmoptysis, or of increasing it while already present, that I cannot help considering the objection a fanciful one. Nay, I am quite sure that very great relief to the congested and oppressed lungs may often be obtained by the rapid removal of blood from the peripheral vessels of the chest:—by cupping the patient freely between the shoulders, or upon the breast. In secondary hæmorrhage from the lungs, in that especially which is connected with tubercular disease, topical blood-letting thus performed is more effectual at the time, and far more safe in the end, than venæsection, repeated, as was once the fashion, from day to day, until the hæmoptysis ceases to recur.

When the fever and congestion are abated; or when there has been no constitutional disturbance, and the hæmorrhage has shown a passive character from the beginning, and when the further loss of blood, so far from being curative in its tendency, is likely to be injurious, then we are to employ those remedies which have been found efficacious in restraining and suppressing hæmorrhages.

Now, of the substances which are held to possess more or less of a specific virtue, when taken internally, in arresting the efflux of blood, the sugar of lead, the *plumbi acetas*, enjoys in this country the highest reputation. And it certainly is a very serviceable remedy. Dr. Paris speaks of it as one of the most valuable resources of physic: and says that in respect to its power over internal hæmorrhage there is nothing *simile aut secundum*. He states also that its use is equally safe and manageable. There is, in fact, no doubt of its efficacy: but most other writers use very cautious language in recommending its employment. Physicians have been deterred

from giving it by the fear of its poisonous qualities; by the dread of producing the disease called *colica pictorum*. Cullen observes, that the preparations of lead are certainly powerful in controlling hæmorrhage, but that they are otherwise of a character so pernicious as to forbid their use except in cases of the utmost danger. Of late years this drug has usually been administered in small doses, and guarded by opium; and it is to this combination that Dr. Paris refers when he declares it to be a safe and manageable remedy. More recently, however, a statement has been made by Dr. A. T. Thomson, which must be considered of much importance if general experience shall show it to be well founded. He was led, it seems, by some accidental circumstance, to suspect that lead acted as a poison upon the animal body, only in the shape of its *carbonate*. And the result of a series of experiments upon brutes satisfied him of the correctness of this notion. He holds, that when the acetate of lead produces the well-known symptoms of the painter's colic, it does so in consequence of its being somehow converted, after its reception into the body, *into* the carbonate: that this conversion may be obviated by a very simple expedient; and that the remedy may then be given with perfect safety in large and efficient doses. The expedient is merely that of administering the lead in draughts containing some dilute acetic acid, which prevents the decomposition of the acetate by any carbonic acid that may happen to be present in the intestinal canal. In this way he tells me he has given as much as fifteen grains daily for ten days together, without any inconvenience, and with most excellent effect upon the hæmorrhage. I have often exhibited lead in this manner; and I have never known it give rise to any unpleasant consequences. At any rate this method of administering it deserves further and careful inquiry.

[We have also administered acetate of lead very extensively in cases of hæmoptysis, and in tolerably large doses, continued, at short intervals, for one or two days, and have never known any injurious or even unpleasant effects to be produced by it. As a means of controlling the hæmorrhage from the lungs we know of no remedy so certain in its effects. In the disease under consideration, we have very generally combined a small portion of ipecacuanha and opium with the acetate of lead. — C.]

In slight cases of hæmoptysis, the mineral acids, with or without alum, are often sufficient; or, if there be feverishness, the saline draught with nitre and digitalis. Of the numberless other drugs which have been vaunted as specifics in hæmorrhage I have very little personal experience; at least in pulmonary hæmorrhage. You may sometimes be urged to give a celebrated quack medicine — *Ruspini's styptic*, which has obtained a high repute, and sells at a high price. This nostrum seems for a long while to have baffled analysis. The late Dr. Wollaston told Dr. Maton that it contained no metallic substance; Dr. Thomson has since announced that it mainly consists of a solution of gallic acid in alcohol, diluted with rose-water. But I believe that all the remedial agents which contain gallic acid are more effectual in another form of internal hæmorrhage, to be considered hereafter. Pure gallic acid itself is now easily procured; and it may be administered in doses of from three to six grains every six hours.

Of *mercury*, as a remedy for pulmonary hæmorrhage, my own experience is as yet too scanty to warrant my recommending it on that ground; but its remarkable efficacy has been strongly vouched to me by some excellent judges who have much employed it.

LECTURE LV.

Pulmonary Emphysema; vesicular and interlobular. Anatomical characters of vesicular emphysema; physical signs; general symptoms; causes; treatment. Interlobular Emphysema; its anatomical characters, symptoms, cause, and cure. Edema of the lungs. Phthisis Pulmonalis.

I HAVE yet one or two morbid conditions of the lungs to consider and to describe, before I go to that which is the most common and most extensively fatal of all its morbid conditions — tubercular phthisis.

There is a state of the lung, or rather there are two or three different states, to which Laennec has applied the name *emphysema*. A very injudicious name it was for him so to impose. We are infinitely indebted to Laennec for the entirely new light which his able researches have thrown upon the morbid anatomy and the pathology of the lungs: but we have to regret that he should have employed, in several instances, a vicious nomenclature. Emphysema is a term that had long been familiar among medical men in a certain sense. It was used to express the inflation of the areolar tissue of the body with air: and surgeons still make much of it as an indication, in cases of fractured rib, that the bone has grazed the pleura, and allowed air to pass into the areolar tissue, and to diffuse itself over the chest and neck, and other parts; so that these parts, when pressed, convey a curious sense of crackling to the finger. But emphysema of the lung, as that term is employed by Laennec, includes dilatation of the air-cells of the lungs, and rupture of the partitions which separate them from each other; and also the infiltration of air into the interlobular areolar tissue, or into the subpleural areolar tissue. In strictness of language these last conditions alone should have been called emphysema of the lung. Laennec has distinguished the two species in this way. To the dilatation of the air-cells, with or without a breach of their partitions, he gives the name of *vesicular emphysema*: “the vesicular (I quote the words of Sir John Forbes’ translation), or pulmonary, properly so called.” Now in truth this is emphysema *improperly* so called. To the infiltration of the areolar tissue in or around the lung with air, *i. e.*, to emphysema of the lung in the old sense of that word, he applies the title of *interlobular emphysema*. We cannot change these denominations now. They have fastened themselves upon

medical language. But it is very fit that you should be aware of their inconsistency with the ancient signification of the same word, and have clear notions of what in Laennec’s nomenclature they are intended to express.

The change called vesicular emphysema was not *unknown*, as a mere morbid condition, before the time of Laennec: but it had been noticed by very few writers, and *practically* it was wholly *unattended to*. Yet it is extremely common: much more so than you would suppose: and when rightly studied it is of great interest too, in relation to the general pathology of the chest. But it is still so new, and it may so readily escape observation, both in the dead and in the living body, if it be not looked for, that I shall devote a

FIG. 59.

Portion of emphysematous lung—the cavities are either formed by simply enlarged air-cells, or by the coalescence of groups of cells.—St. Bartholomew’s Museum, xiv. 11.

somewhat more minute attention to it, on those accounts.

Laennec was undoubtedly the first to put emphysema pulmonum upon the list of definite and cognizable diseases; to point out its frequency; and to collect its symptoms. But when he affirms that, before his time, the pulmonary change which con-

stitutes the disorder was misunderstood by nearly all those persons who had noticed it, he scarcely does them justice. "All of them (says he) seem to have thought that the derangement in question consisted in the infiltration of the cellular substance of the lungs with air." He inconsistently adds, "Ruysch and Valsalva are the only authors, as far as I know, who have observed in individual cases the dilation of the cells;" and with still greater inconsistency he proceeds to quote, from Morgagni, the following passage, in which this dilatation is very clearly described: "*Sinistri pulmonis lobus superior, quâ claviculæ spectabat, vesiculas ex quibus constat mirum in modum auctas habebat; ut nonnullæ avellanæ magnitudinem æquant; cæteræ multo minores erant.*" You will find the same change noted by Dr. Baillie, in his *Morbid Anatomy*: and by earlier writers than he.

Vesicular emphysema, then (to adopt Laennec's phraseology), consists in dilatation of the air-cells. The enlarged cells become misshapen also in many cases. They vary in magnitude from that of a millet-seed to that of a swan-shot; nay, the cavities may even reach the size of a nutmeg or of a hen's egg: but when they are as big as this—and *a fortiori* when they are still bigger—the distension and vacuity are, no doubt, the result of the union of several air-cells, broken into one by the stretching or destruction of the partitions that naturally divide and isolate them. You may see the dilated vesicles very plainly through the pleura, if you carefully examine the surface of the lung. They appear to the naked eye as the healthy vesicles appear when seen through a magnifying glass. Sometimes all the vesicles belonging to one lobule are enlarged, while those of the adjoining lobules are of the natural size. In that case the emphysematous lobule is conspicuous both by its peculiar colour, and by its protrusion. The surface of the lung is often rendered quite irregular and uneven by projections of this kind. Sometimes one large globular prominence is seen, like a bubble on the water, or like a little bladder springing from a footstalk: but if you examine it closely you will generally find that the footstalk is merely a constriction at the surface, and that there is as large a cavity beyond it, in the lung, as there is without. These bullæ you cannot slip about, by pressure, from one part of the pleura to another.

The unevenness produced by vesicular emphysema upon the outside of the lung is manifest enough, when looked for; but the same condition of the air-cells exists also within, and *there* it is *not* so readily perceptible. The fluids which the lung contains, obscure all distinction of parts when the organ is cut. The best way of getting a fair view of the dilated cells, as they appear in the substance of the lung, is to inflate the emphysematous portion, by blowing air in at the bronchial trunk which belongs to it, and then tying that trunk to prevent the escape of the air. The inflated lung should be hung up in a current of wind, so that it may quickly dry; and during the drying process it should, from time to time, be re-inflated: for else the included air gets out somehow, and the piece of lung shrinks and shrivels up. When it is quite dry, if a section of it be made with a thin sharp knife, the altered state of the air-cells, some of which are *more* and some *less* dilated, will be very conspicuous.

No part of the lung is exempt from liability to these morbid changes: but generally they are limited to certain portions of the organ, and they are much more common and more pronounced at its loose anterior borders, and near its summit in front, than anywhere else. Both lungs appear to be alike obnoxious to the disease; which seldom affects the one without affecting, in a greater or less degree, the other also.

The parts that are emphysematous are usually paler than the rest, and sometimes they are quite white. In extreme cases the surface of the lung presents a sort of piebald appearance; large patches of it looking as if they had been bleached. This pale colour is oftenest seen towards the free edges of the lung. Sometimes those edges are rounded and thick; sometimes thinner, and folded back; while sometimes the

FIG. 60.

Vesicular emphysema.

margin is blown out, as it were, into an irregular fringe; some of the inflated portions remaining connected with the lung by slender pedicles, and thus forming *appendices* to it of a light yellow colour. I presume that what was thought and called a fringe of fat, garnishing the edges of the lung, in the body of King George IV., was of this kind. At least I have never seen, nor heard of, any other example of fat deposited in those organs. If you hold the emphysematous border between your eye and the light, you perceive that it is translucent: if you prick it with a pin, the puffy part surrounding the puncture sinks down; which shows that the dilated vesicles communicate together.

An emphysematous lung is not only paler, but drier also than ordinary: and for the same reason. It possesses fewer capillary blood-vessels, less blood, and consequently less moisture. It is dry and light, and floats high upon water, like a bladder filled with air.

If you take such a lung out of the body, having its surface embossed with irregular groups of enlarged air-cells — and if you inflate that lung, by blowing into the bronchi — the emphysematous portions will often *seem* to sink in, and flatten, and return to the ordinary level as the whole lung becomes distended. In point of fact, however, these portions remain permanently dilated, and the other parts near the surface, when they are sound and permeable, rise, as the air enters them, until the whole is smooth and even. Air is shut up in the emphysematous portions, which do not subside, as the adjoining portions do, when left to the agency of their proper elasticity. Hence you will see how it is that, when the vesicular emphysema is extensive, so as to occupy nearly the whole of the lung, the lung becomes apparently too big for the case in which it is contained. Not only does it *not subside* when the sternum is raised, and the pressure of the atmosphere is admitted to its external surface; but it even *protrudes*, the moment that the opening is made. When you handle such a lung, it gives a very different sensation to the fingers from that produced by pressing a healthy lung. It feels like a down pillow. It crepitates less; the air is less easily forced out of it, and escapes slowly, with a slight hissing noise.

The nature of the morbid state that I have been describing suggests at once the notion of some physical cause for it. But the mode, and the mechanical conditions, of its production, have been much misunderstood. I must confess that on previous occasions I have given you what I now know to have been an erroneous account of the generation and relations of vesicular emphysema. The permanent dilatation of the pulmonary vesicles is not attributable, as in common with others I formerly supposed, to the accumulation, imprisonment, and distending force of air shut up within the vesicles by obstructions in the air-tubes. Obstructions in the air-tubes cause an emptying of the portions of lung to which they lead—a collapse, and not a distension, of the vesicles. It is to Dr. William Gairdner that we are indebted for more correct views of these structural changes, so opposite in character; and of their mutual relation. He has shown that, in a vast majority of instances, pulmonary emphysema is a consequence of pulmonary collapse. I have always indeed been of opinion that emphysema does not occur as a primary and independent disease; that it is in every case a secondary change, the result of some pre-existing thoracic change. It is never met with alone: and according to Dr. Gairdner's testimony, pulmonary collapse is by far its most frequent concomitant. Take notice, if you please, that these two unnatural and opposite deviations from the healthy state have each its favourite place: collapse affecting chiefly the posterior portions, near the roots of the lungs, while emphysema occupies generally their fore-part, and above all, their anterior borders. It is found, too, that the tubes which belong to the emphysematous parts are rarely obstructed. Air blown into them reaches with facility the dilated vesicles. The tubes of the collapsed parts are clogged with viscid mucus. It can scarcely be doubted that collapse of certain portions of the lungs leads to emphysema of certain other portions. But it is not mere condensation and solidification of the pulmonary substance that produces emphysema elsewhere in the lung. Emphysema is not commonly found coexisting with hepatization alone, nor with solidity arising from the deposit of tubercular matter. What is there, then, peculiar to the condensation of collapse that should render it so fertile a source of subsequent emphysema? It is this — that collapse implies a diminution in the *bulk* of the lung, and that other modes of condensation are not necessarily attended with such diminution. For every portion of lung

closed by collapse there must be a proportionate loss of bulk. But since there can be no vacuum, it follows that, as the thorax expands, more than the standard quantity of air must enter those tubes and vesicles which are not involved in the collapse. And if the quantity exceed a certain amount, dilatation of the vesicles must needs ensue. There may indeed be atrophy and reduced bulk under other forms of condensation, and if so, there may arise a correspondent emphysema. The shrinking up of one part causes undue inflation of other parts, which also may thus be rendered permanently unsound. The old explanation was founded upon the supposed effect of pressure, made during strong expiratory efforts, upon air shut up in certain vesicles. But in truth no partial pressure can be so applied. It is when a portion of the lungs has lost its expansile power, and those organs rise in pursuit of the widening parietes of the chest in inspiration, that some of the permeable portions are apt to be stretched beyond their healthy dimensions by the force of the entering air.

Remember then that vesicular emphysema is a mechanical and complementary (though by no means a compensating) effect of the condensation and diminished bulk of other portions of the lungs; and not a substantial affection in itself. Disease of one kind in one part, brings about disease of an opposite kind in another part of the same organ.

The state of the lung, as discovered after death, being such as I have attempted to describe, you will naturally be inquisitive to know by what signs the existence of a condition so remarkable is revealed during life. First, then, when the emphysematous distension is considerable in amount, and extensive, it is associated with notable alterations in the shape and movements of the chest. The lung having lost much of its elasticity, does not subside as a healthy lung subsides. The act of expiration is arrested and incomplete. Consequently the thorax remains nearly in that position which it assumes after inspiring. It is prominent and rounder on the diseased side; or on both sides, if both lungs be affected; but it is apt to be irregularly prominent, and unsymmetrical; to bulge here and there in correspondence with the bulging of the lung within. The ribs lie less obliquely than they should do, and the chest is, therefore, more cylindrical, or barrel-shaped. The clavicles are ill-defined in such persons. They are so, as you know, in *fat* persons; wherefore this aid to the diagnosis is of most value in those who are *spare*. In them it is a valuable sign, for it is simple and obvious. The distended lung presses upwards, as well as in other directions, and tends to efface the depressions which naturally exist both above and below the collar-bone. This symptom is the more to be depended on, if it present itself on one side only. It is readily distinguishable, by means to be mentioned immediately, from a similar fulness of the subclavian region produced by a large collection of liquid within the pleura. The manner of breathing is instructive also. The ribs, never receding within their proper limits after expiration, can move but little during inspiration: and the breathing is in a great measure abdominal.

Now all these signs are physical signs. But what, in the second place, are the *auscultatory* physical signs? Why, in the emphysematous regions, which commonly are also the most bulging, percussion yields an unnaturally clear and resonant sound; while auscultation discovers a very indistinct vesicular murmur. The two modes check and explain each the information afforded by the other. Percussion ascertains that there is air beneath the part struck: auscultation ascertains that there is little or no *air in motion* beneath that part. It follows, therefore, that there is stagnant air; air shut up in the enlarged air-cells, or air interposed between the ear and the lung in the cavity of the pleura: air at rest, in fact. I say the respiratory murmur is very feeble. This partly depends upon the limited play of the ribs, partly and chiefly upon the circumstance that the air is imprisoned in the dilated cells. When none enters or leaves them during respiration, no vesicular breathing can be heard: and then we must call in the aid of other considerations to determine whether the air be contained in the cavity of the pleura, or in the emphysematous lung.

Pure pneumothorax is extremely rare. Pneumothorax with liquid effusion is easily recognised by its proper signs. If these be absent, we conclude that the stagnant air occupies the lung, and not the pleura: and this conclusion is strengthened if the unduly resonant part be prominent also. Almost all writers on this subject follow Laennec in stating that *dry* crepitation may be heard in the emphysematous parts. It may be so; but if so, I cannot distinguish it. I mean that I know no crepitation but

that which is moist, and which proceeds from the formation and rupture of bubbles, as air passes through liquids in the bronchial tubes. But some people believe that they can hear a dry crackling, such as may be produced by inflating a portion of dry areolar tissue out of the body, or a dry bladder. You will try this by your own experience. I do not deny that such a sound occurs: I only say that if it do occur, I cannot tell when I hear that dry sound, and when I hear large moist crepitation. But I more than suspect that no such sound is given out by an emphysematous lung; and that the sound heard is really large crepitation in the neighbourhood of the dilated cells: for emphysema is very often accompanied by catarrh: and the sounds in question, authors agree, are not permanently audible.

So much for the physical signs of emphysema pulmonum. The *general signs*, when the change is extensive, are habitual shortness of breath, with occasional paroxysms of extreme dyspnoea; cough, which, however, is far from being a constant symptom; palpitation in most instances as the disease advances; and more or less œdema of the ankles. Usually the appetite remains unimpaired, and the patient does not lose flesh. The disorder is unattended with fever; and is essentially chronic.

The paroxysms of urgent dyspnoea are frequently concurrent with, and apparently excited by, attacks of smart bronchial catarrh; but they sometimes arise without any obvious cause. They are apt to come on suddenly, in the night, and the patient is obliged immediately to sit up, and even to open the doors and windows of his bedroom, that he may breathe more freely. In one word, he undergoes a paroxysm of *asthma*. These attacks become more frequent and more severe as the patient and the disorder grow older. They are attended with much wheezing; and in the lower posterior part of the lungs crepitation is generally audible. At first the palpitation of the heart, and œdema of the feet, abate and cease as the violent dyspnoea goes off: but at length these symptoms become permanent.

We see a reason in the physical condition of the thorax, why the breathing should be more oppressed, and why the paroxysms of orthopnoea should occur more frequently, *in the night*. Whenever the respiration is principally abdominal, it is apt to be embarrassed by the recumbent posture, which throws a part of the weight of the viscera of the belly upon the diaphragm. The horizontal position is always ill borne by these patients; and, for similar reasons, flatulence or fulness of the stomach, however caused, distresses them.

Cough, as I observed before, is an occasional, but by no means an essential accompaniment of vesicular emphysema: the expectoration, when there is any, is thinnish, like gum-water, and full of foam.

The disease of broken-winded horses is pulmonary emphysema; and Sir John Floyer, in his *Treatise of the Asthma*, published in 1698, sets forth, in the quaint language of that olden time, both the alteration which Laennec thought he had been the first to describe, and the manner in which he supposed it to arise. His observations respecting the lungs of horses are equally applicable—and he no doubt intended to apply them—to the human lungs. After speaking of “the broken wind, from the rupture or dilatation of the bladders of the lungs, by which the air is too much retained in the bladders, or their interstices, and thereby produces a permanent flatulent tumour”—and stating that “these horses wheeze much after filling their stomachs by water or food, because that keeps up the diaphragme”—he goes on thus:—“As it happens in external flatulent tumours, they at first go off and return, but at last fix in permanent flatulent tumours; so it is in the flatulent asthma, the frequent nervous inflations induce at last a constant windy tumour or inflation; and it ought to be considered how far holding the breath in hysteric fits, or the violent coughing in long catarrhs, or the great distension of the lungs by an inflammation in the peripneumonia, may strain the bladders and their muscular fibres, and thereby produce the same rupture or dilatation or hernia as happens in the broken-winded. This must be observed by the help of the microscope; and if the air blown into any lobe will not be expelled thence by the natural tone or muscle of the bladders, that the lobe may again subside of itself, ’tis certain some injury is done to the ventiducts; the bladders are either broken, and admit the air into the membranous interstices, or else they are over-distended like a hernia in the peritoneum; and this will produce an inflation of the whole substance of the lungs, and that a continual compression of the

air and blood-vessels, which will produce a constant asthma." Really this is a capital piece of pathology for the seventeenth century.

I have said that emphysema is always (in my opinion) a consequence of pre-existing disease or disorder of the chest. But I ought also to say that some persons believe it to be occasionally a congenital and idiopathic affection. You may often trace back the habitual shortness of breath to the period of infancy. Patients will tell you that from their earliest recollection they have been easily put out of breath: that they were never able to engage heartily, and to the same extent with their companions, in the active sports of childhood. It is a fact, too, that the complaint is traceable, from one generation to another, in certain families. Being thus often present at an early age in children born of emphysematous parents, the emphysema, in such cases, is set down as a vice of the original bodily formation. I am not convinced by this mode of reasoning. The facts upon which it rests show simply that the disorder may run in families, and that the tendency to its ordinary cause is sometimes inherited; that ordinary cause being partial collapse of the lungs. The same low degree of vitality or weakness of fabric, which favoured the production of such collapse in the parent, is repeated in the offspring, and imparts the same predisposition. Young children are moreover very liable to severe attacks of obstructive bronchitis, and therefore to lobular collapse and its consequences. We know that lobular collapse is also a frequent legacy of hooping-cough in the early periods of life. After the cough has ceased, however, the shortness of breath which it leaves behind is easily overlooked, until, with the increase of the emphysema, it forces itself into notice. For when once the morbid process has begun, it tends, slowly often, but surely, to its own augmentation. As the cells dilate, the capillary blood-vessels distributed over their parietes are gradually compressed and emptied: and many of them are, at length, completely obliterated. Hence, not only an exsanguine condition of the pulmonary tissue, but atrophy also of the intervesicular partitions, which become first thin, then tattered and imperfect. In dried specimens of emphysema you see very plainly the remains of the former walls of separation between the vesicles.

It is this interference with the nutrition of the lung which causes vesicular emphysema to be always a *progressive* disease. We see why it is that, speaking generally, the extent of the morbid change is proportioned to the age of the patient: why paroxysms of severe dyspnoea at length supervene; and become more and more frequent and trying. The function of the lung becomes year by year more limited; until it can no longer bear, without a struggle of distress, that further encroachment upon its office and capability which a slight catarrh, rapid movements of the body, a distended abdomen, or even the recumbent posture, may be sufficient to produce.

Vesicular emphysema may arise then, and receive increase, from various disordered conditions that precede or accompany it, and of which it is the effect: from any condition which renders a portion of the lung impermeable by air, and at the same time diminishes its bulk. On the other hand, it has been held to be, and I believe that it often is, itself the cause of subsequent disease, not merely in the lung, but in other parts; and above all, of disease in the right chambers of the heart. The smaller blood-vessels, as I have shown you, are gradually effaced as the dilatation of the air-cells proceeds; the emphysematous lung is evidently in a state of comparative anæmia, and incapable of admitting all the blood which is due to it from the pulmonary artery. In other words, the right side of the heart does not empty itself with its accustomed ease. Hence increased muscular contractions of the right ventricle: and a yielding of its walls to the augmenting pressure of the contained blood. And this embarrassment of the circulation in the right side of the heart is aggravated at those periods when the paroxysms of urgent dyspnoea occur. Now nothing is a more sure cause of anasarca than a permanent dilatation of the right cavities of the heart: and this influence of the unsound lung upon that organ is clearly seen in the palpitations to which such patients are liable, and in the œdema of the feet and ankles which often becomes manifest at the same time.

Dr. William Gairdner has, however, shown good reasons for believing, and has fortified those reasons by a large appeal to the morbid anatomy of the parts concerned, that the dilatation, with or without hypertrophy, of the right chambers of the heart, thus commonly accompanying pulmonary emphysema, is not always — is not ever mainly — the consequential effect of that emphysema; but that the pulmonary and

the cardiac change are both of them effects of the same cause, namely, of diminished bulk of the lung, in whatsoever way that may have been brought about. The expansion of the chest in inspiration, which tends to dilate the air-vesicles of such a lung, tends also, and in the same way, to dilate the cavities of the heart.

The main conditions of the production of vesicular emphysema being those already set forth—that is to say, impermeability of part of the lung and reduction of its bulk—we see how that change *may* be produced by *pressure*, when the pressure implies condensation and atrophy of the pulmonary substance: by tumours, therefore, within the thorax, by an enlarged heart, by aneurism of the thoracic aorta, by deformity of the chest from a crooked spine, and even by tight lacing. Certain other alleged causes, enumerated by Laennec, because they fell in with his theory of the production of the disease, such as violent straining efforts, blowing on wind-instruments of music, and the like, have probably no such operation.

The relations between pulmonary emphysema and tubercles of the lungs require also a short notice, for they have been misunderstood. Louis, who has analysed with his accustomed care and exactness a considerable number of cases of emphysema, states that the disease is seldom complicated with tubercles. It has even been affirmed that the two disorders are antagonistic of each other, and incompatible: and this doctrine has led to the absurd project of attempting to prevent phthisis by creating emphysema. The latter exploit would probably be even more difficult to achieve than the former.

The simple truth appears to be that vesicular emphysema bears precisely the same relation to tubercle as to other structural diseases of the lung. The mere deposit of crude tubercular matter solidifies a portion of lung, and impairs its permeability, without reducing its bulk. The mere deposit of crude tubercular matter has, therefore, no tendency to generate emphysema: and when there is no other pulmonary defect, these two morbid conditions seldom meet in the same lung.

But tubercular phthisis is very often, most commonly indeed, attended in its progress with *cavities* in the lung; and the tissue surrounding these cavities is often in a state of atrophy. I am touching by anticipation upon the terrible disease which will next engage our attention. Such cavities may be increasing in size, and ill-defined, with weak and yielding walls; and then they, rather than the sound air-cells, will be likely to enlarge under the expanding force of inspiration, so as to balance the amount of atrophy. Large or numerous cavities, therefore, with flaccid walls, are unfavourable to the development of vesicular emphysema, and may be said to guard the lung against its occurrence. On the other hand, when the cavities are tending to heal and contract, and are surrounded (as under such circumstances they usually are) by dense fibrous tissue, and when they are small and few in number, and much of the lung is sound, the expansion during a full inspiration will then tell upon the air-cells, and favour the production of emphysema.

Once more—I shall have to show you that tubercular deposits may issue in a sort of cure, and leave in the lung depressed cicatrices, involving often cretaceous relics of the tubercles. Here we have manifest loss of bulk, while a large portion of the pulmonary tissue may be sound. Here we have the conditions of the generation of vesicular emphysema, and accordingly it is acknowledged by the best observers that vesicular emphysema is almost universally present in lungs that bear those marks which are considered to be evidences of recovery from phthisis.

Such are the views put forth by Dr. William Gairdner of the relations between tubercle and emphysema of the lung. They are novel, they are interesting, and to the best of my judgment they are true.

I must beg you to bear in mind that emphysema of the lung is one, and a very common, cause of *asthma*. The asthma so arising is less perilous than that which proceeds from certain other organic changes, to be described hereafter. Vesicular emphysema indeed, in its simple uncomplicated form, is seldom attended with much danger. When it proves fatal, it is so in consequence of the superaddition of some other disease. Laennec states very truly, that, of all the varieties of asthma, this is the one which affords the patient the best hope of a long life.

The condition that I have been describing, when once it has fairly been established, can scarcely admit of a cure. We shall do our patients good, not by any treatment addressed to the existing emphysema itself, but by guarding them against those cir-

circumstances which are likely to aggravate it; and by mitigating or removing those other disorders with which the emphysema is apt to be combined. Whatever is calculated to put the patient out of breath is bad for him. It is observed that they who, having emphysema, are obnoxious also to catarrhs, during which the dyspnoea is singularly increased, are much more free from such attacks in the warm weather of summer, than in the winter. This explains the beneficial influence of a judicious change of climate upon such persons, and it points to the necessity of warm clothing in the colder seasons for those who are obliged to remain in this country. The feet especially should be kept dry and warm; and the liability to catarrh may be sometimes diminished by the use of the cold shower-bath, in the way I formerly recommended. During the fits of extreme dyspnoea, you may hear the expiratory wheeze remarkably loud and protracted; and if, withal, you hear any small crepitation, indicative of pneumonic inflammation, you will do well to cup the patient moderately between his shoulders. This will always give relief to loaded lungs, whether there be inflammation present or not. But the great assuager of the dyspnoea in this disorder is opium: and especially opium combined with ether. Half a drachm of Hoffman's anodyne, with a third of a grain of the acetate or muriate of morphia, in camphor julep, will operate like a charm often, in quieting the whole system, and removing the difficulty of breathing. This circumstance would lead us to suppose that the access depended, in part at least, upon a spasmodic state of some of the muscles concerned in respiration. To this question I shall revert when I speak of asthma as a separate disease. At any rate you will find that some such formula as I have just mentioned will stand you in good stead when you have to deal with asthma engrafted on emphysema. And I may add, that this is a case of exception to a rule I formerly laid down. You need not be deterred from giving a full dose of opium by the blueness, which is temporary, of the patient's lips and countenance.

The *interlobular and sub-pleural* emphysema of the lungs is a species of *true* emphysema, the air being contained in the meshes of the common areolar tissue.

When it appears on the surface of the lung, it may be distinguished from the bladder-like prominences, which sometimes form there by dilatation of the air-cells, in this way: the bullæ which are situated in the areolar tissue connecting the pleura with the lung, may be made to move hither and thither under pressure; whereas those which result from the protrusion of an enlarged cell or cells cannot be made thus to change their place. This sub-pleural effusion of air is sometimes enormous. I have seen it as large as a hen's egg. Bouillaud mentions a case in which the bladder or pouch was equal to the size of a stomach of ordinary dimensions. It proceeds, I presume, from the rupture of a superficial air-vesicle. Sometimes, as I mentioned before, the *pleura also* gives way, and air is poured into the cavity of the thorax. More commonly the membrane remains entire, and then these large bubbles of air may be seen upon the surface of the lung.

Of interlobular emphysema I can give you but little account except from the observations of others. I have never seen more than one well-marked example of it. The lobules of the lungs cohere together by means of areolar tissue, which is dense and close in the natural state, but which admits of considerable expansion when it is inflated with air. If the emphysema be slight in degree, the lozenge-shaped spaces visible on the surface of the lung are defined by little bubbles of air, that look like beads strung upon a thread. But in extreme cases the lobules are fairly blown asunder by the air; the partitions between them increase in width, and are said to be sometimes as much as an inch broad. They are broadest towards the surface of

FIG. 61.

Interlobular emphysema.

the lung, and narrower towards its roots; and exhibit somewhat of the arrangement seen in the section of an orange, the septa radiating and diverging from a centre. If the areolar tissue could be taken out, there would be left cracks and clefts in the lung. When the interlobular emphysema penetrates to the roots of the lung, the air readily passes into the areolar tissue of the mediastinum, and thence to the subcutaneous tissue of the neck and chest—and then we have the genuine emphysema of authors who wrote prior to Laennec.

There is this material difference between vesicular and interlobular emphysema; that the one is commonly slow and gradual in its formation, the other sudden. The permanent dilatation of the air-vesicles is the work of time. They yield, and lose their elasticity, and break into one another, only by degrees. The interlobular effusion of air may be effected in a few minutes or seconds. It is caused by *violent* straining efforts; such as those made by a woman in childbirth, or by any one who exerts himself to lift a weight which is too much for him. A deep inspiration is taken; then the glottis is voluntarily closed, and a strong expiratory effort is made. Some rupture must take place and form a communication between the air-vesicles and the areolar tissue; but such rupture has never been *traced*, nor is it likely that it should be.

They say that this form of emphysema is revealed also by large dry crepitation; why it should, is not evident. I can only say of that sound, as I said before: it may exist, and it may be distinguishable from large *moist* crepitation, but my ear is not delicate enough to distinguish it: and to speak the truth, I doubt exceedingly whether any such sound really occurs at any time. But do not let my doubts infect you. Try for yourselves; and till you have had opportunities of investigating this point, consider it as *adhuc sub judice*.

Again, they say that the noise of friction denotes the existence of interlobular and subpleural emphysema. On this point I can give you no information of my own knowledge. That you may sometimes hear the costal pleura rub against the pulmonary during inspiration and expiration I know. I have often heard that sound (as I mentioned to you before) when the membrane has been roughened by pleurisy. But that a soft, smooth, moist lung, though embossed by emphysema, will give rise to a rubbing sound, I do *not* know. It may be so, but it has never occurred to me to hear it.

We may be more certain that interlobular emphysema has arisen when, immediately after some violent straining effort, considerable dyspnoea and oppression ensue, and presently the subcutaneous areolar tissue becomes emphysematous. You will understand how rapidly the inflation of the areolar tissue may take place if you ever saw a butcher blow up that of a calf which he is in the act of skinning.

As interlobular emphysema differs from vesicular emphysema in its seat, in the suddenness of its formation, and in its cause, so does it differ in its curability. Under favourable circumstances it will soon cure itself—the air will be reabsorbed, and the dyspnoea cease. I do not know that we can do much by art to accelerate that process. If the dyspnoea be extreme, it will be relieved by blood-letting; and if the air make its appearance, and can be felt, crackling, beneath the skin, you may let it out by making a few punctures with a lancet, and the deeper-seated emphysema will be lessened as the air-escapes. I believe that this interlobular emphysema is more common in infancy than in any other part of life; on account, I suppose, of the greater delicacy and tenderness of *all* the tissues at that age.

The interstitial areolar tissue of the lungs, as well as the air-cells, is liable to be filled not only with air, but with serous fluid; and this constitutes *œdema of the lungs*; a condition which is by no means uncommon, and one of which you ought therefore to be aware; but it need not long occupy our attention at present. When a lung, or a portion of a lung, is anasarcaous (and you will often find that the œdema is limited to the most depending part of those organs), it is generally of a pale grey or yellowish tint; is heavier than healthy lung, and less crepitant; and pits more on pressure—is *doughy*. And if the œdema be extensive, the lung does not subside perfectly when the chest is laid open. If incisions are made into such a lung, a thin watery fluid flows out, more or less spumous; and if the lung be well squeezed, the whole of the liquid may be expressed; and then it will be obvious that the texture

of the organ is sound, but that it had previously contained less air than usual, in consequence of the presence of the watery fluid.

This condition of the lung seldom takes place except as a part of general anasarca: and we may discover its existence, first by noticing that there is dropsy of the areolar tissue in other parts; secondly, that the patient has dyspnoea; and thirdly, by hearing crepitation, produced by large bubbles, at the lowermost portions only of the lungs. Into those portions the liquid gravitates; just as it sinks into the ankles when the patient sits up or walks about. There is still air in the œdematous portion; so that percussion still gives a hollow sound; as hollow at least on the one side as on the other. With the air there is also liquid, which transudes, I suppose, from the areolar tissue, or is exhaled from the surface of the membrane: and the liquid is from time to time coughed up and expectorated. Sometimes, however, there is but little expectoration. What does come up is chiefly aqueous, with occasionally a piece or two of mucus floating upon it; and it is somewhat foamy also.

This œdema or anasarca of the lung is symptomatic of other disease; generally of disease of the heart or great blood-vessels; and it is capable of no other rational treatment than such as is suited to the original disorder: and therefore I have nothing further to say about it now.

I proceed, in the next place, to that most prevalent and lamentable disease of the lungs, which is well known to everybody, under the titles of *pulmonary consumption* and *tubercular phthisis*. And without pausing to make any general reflections, touching facts which must be familiar to you all—the fatal and almost hopeless character of the disease, and the havoc it produces among the young, the most gifted, and the most beautiful, of the human race—I shall commence by inquiring into the *morbid anatomy* of tubercular phthisis; which will naturally introduce us to the consideration of its symptoms, causes, treatment, and general history.

Phthisis, you know, means a wasting away, or a consuming; but of late years the term has been restricted to that *species* of wasting disease, which consists in the occupation of the lungs by tubercular matter, and the changes which that matter *suffers* and *works*. But it would be an error to suppose that the disease is restricted to the *lungs* in these cases. The lung disease would be sufficient at length to destroy life; but its mortal tendency is aided and accelerated, in most instances, by disease of a similar character, situated in other organs. “The *pulmonary* consumption (as Dr. Latham justly observes) is no more than a *fragment* of a great constitutional malady.” But that malady plays its part most conspicuously in the lungs. I shall notice its complications as I go on; but I am desirous of cautioning you in the outset against supposing that tubercular phthisis is *exclusively* a pulmonary disease.

Before I proceed to a more particular description of the changes that, in the progress of consumption, are wrought in the lungs, I must briefly recall to your recollection certain points, relating to tubercular disease in general, which were brought before you in an earlier part of the course. The formation of tubercles is closely linked with the existence of the scrofulous diathesis. Tubercles themselves are composed of unorganized matter, deposited from the blood, of a yellowish colour, opaque, friable, and of about the firmness and consistence of cheese. This is what all pathologists agree in regarding as the true tubercular matter. It is most commonly deposited on the free surface of mucous membranes; and not unfrequently amidst areolar tissue. You will remember that tubercles are not necessarily, as some have supposed, of a round shape. Their form depends upon the nature of the tissue in which the tubercular matter is deposited. Wherever it is laid down, it is liable to increase in quantity by the continual accretion of fresh matter of the same kind. Hence, when a speck of this peculiar matter is deposited in any soft uniform tissue—such as the brain, or the areolar membrane—there being no inequality of pressure from any quarter, it preserves a spherical or globular form as it grows larger. But taking the lung, with which we are at present chiefly concerned, the round form is sometimes real, sometimes apparent only. It is real when the tubercular matter fills up, or lines, and therefore takes the shape of, the pulmonary vesicles. So it is when a number of these, contiguous to each other, coalesce by the increase of deposit, and compose one large globular mass. And you may often catch the tubercles, if I may so say, in the process of forming these large rounded masses; *i. e.* you may see them arranged in

circular groups or clusters, the interstices between them becoming gradually smaller and smaller. But when, as is often the case, the tubercular matter is laid down in the smaller ramifications of the bronchi, it assumes a cylindrical shape. This you may ascertain by carefully following the branching of the air-tubes: but in the manner in which the lung is usually divided by the scalpel, you see merely sections of these cylinders; and then the round form is apparent only. If the tubercular matter come to fill one of these smaller air-tubes, and also all the vesicles to which that tube conducts, then the new substance, when fairly displayed, represents a branch, with a cauliflower termination; like a twig with a bunch of leaves at its extremity. You may see these appearances delineated, from nature, in Sir R. Carswell's admirable lithographic drawings.

If this account of the formation of tubercles, as explained by Sir R. Carswell, be the true one; — of which I entertain little doubt; — it will follow, as a matter of necessity, that no alteration *can* take place in the tubercular matter, after it has once assumed the solid form, except through the agency of the parts around and in contact with it. No vital change can originate in the inorganic tubercle itself.

Fig. 62.

Miliary tubercle, scattered throughout the pulmonary tissue, forming translucent, greyish, and circular points, of the size of pins' heads.

Besides this true and undisputed species of tubercle, you will often find the lungs more or less thickly studded with a number of small granules, of firmer consistence, almost as hard as cartilage, semi-transparent, and of a bluish-gray colour. Respecting the nature of these granules — which are sometimes called *miliary tubercles*, some-

Fig. 63.

Microscopic appearance of miliary tubercle. The drawing to the left shows the site of the deposit and its relation to the pulmonary tissues; the effusion has taken place into the air-vesicle, which is distended into a globular ball. The drawing to the right exhibits a section of miliary tubercle without the bronchules, surrounded by congested vessels.

times the *granulations of Bayle*, who first described them — many different opinions are entertained. Laennec considered them to represent the incipient stage of the opaque yellow substance; and he calls them accordingly *nascent tubercles*. Andral

believes that they are simply some of the pulmonary vesicles rendered solid and hard by chronic inflammation. Sir R. Carswell explains their formation in this way. The membrane lining the air-passages secretes from the blood, not only the matter of tubercle, but its own proper fluid; whence it sometimes happens that a dull yellowish point of tubercular matter becomes enclosed and set, as it were, in a small pellet of grey, tough, semi-transparent mucus. Whatever may be the true theory respecting

FIG. 64.

Microscopic appearance of a mass of miliary tubercle, in close aggregation.

these little bodies, it is certain that they acknowledge some intimate connexion with the true cheesy tubercle. Both occur in the same persons, in the same lungs, in the same parts of the lung. One very seldom occurs without the other. They both belong essentially to the disease we are considering—pulmonary phthisis. Louis, a minute and faithful observer, states, that the granules present, at a certain period of their development, a central opacity. Upon the whole, it seems probable that Laennec's doctrine, in regard to the relation subsisting between the grey semi-transparent granule and the yellow opaque tubercle, was well founded.

He was wrong, however, in some other points, especially in his statement that the softening of tubercles begins in their *centres*. Sir R. Carswell has shown how the *appearance* of a central softening arises, first, in the smaller tubercles; secondly, in the larger agglomerated tubercular masses. The morbid secretion is deposited, principally, upon the mucous surface—upon the inner lining of the air-cells, and of the bronchial tubes communicating with them. Now it may so accumulate as to *fill* those cavities; and then, sections of them will represent the crude tubercles of Laennec. But it may only *line* the cavities: it may leave a central vacuity, containing mucus, or other secreted fluids; and if the lung be cut across under these circumstances, the divided air-cells will look like *rings* of tubercular matter grouped together; and so also will the divided bronchial tubes. We then have the *appearance* of tubercles with central depressions, or soft central points; and Laennec was deceived by those appearances.

But the larger masses begin also, he says, to soften at the centre. True: we do find the process of softening going on at several points within them at the same time. The masses, you must bear in mind, are formed by the growing together of many smaller tubercles; and the areolar tissue, with the other tissues which originally separated these tubercles, still exists, though it ceases to be visible. At length, under the augmenting pressure, or some other influence, it suppurates; and in this way the tubercular mass is broken down. Now this is the very process by which the tubercles are at length, often, expelled from the body. They increase till the surrounding parts take on inflammation, either from the increasing pressure, or from some accidental cause. The inflammation thus excited, occurring in scrofulous persons, has the scrofulous character. The thin pus which it throws out pervades and loosens the tubercular deposit; a process of ulceration goes on in the surrounding textures; and, at last, the softened scrofulous matter is gradually coughed up and expectorated.

This explanation of the mode in which the tubercles are formed, and increase, and

soften, and are removed, has been given to the world within the last few years, by Sir R. Carswell; and it is much the most simple and probable of any that I have seen. It is, moreover, perfectly consistent with the best ascertained facts concerning the progress of tubercular disease. You will find numberless theories broached by different authors on this subject, if you like to look for them; but I do not think you will find any more satisfactory than Sir R. Carswell's. And having recalled these

things to your memories (for it is some time now since I mentioned them before), we may go on to the further consideration of the morbid anatomy and pathology of tubercular phthisis.

It is a remarkable and very important fact, that tubercles, when they affect the lungs, are not deposited at random, or indifferently in all parts of those organs. It is in the upper lobes, and in the upper and back parts of those lobes, that, in nineteen cases out of twenty, and in more than that proportion, we meet with tubercles when they are few. It is in the same part that they are largest, and most numerous, when they are scattered throughout the whole lung. It is here, also, that they first ripen, and grow soft, and become ready for expulsion through the bronchi and trachea: consequently, it is here that we have the most frequent, the most numerous, and the largest excavations in the lung—what are technically called *vomicæ*. And the number and magnitude of the tubercles and of the *vomicæ* gradually diminish from the summit of the lungs downwards.

Now these are not merely *curious* facts: they have a most important bearing upon the diagnosis, in cases that might otherwise be doubtful. It is a rule which has but few exceptions—just enough to establish its claim to be a rule—that the favourite habitat of pulmonary tubercles is the upper part of the superior lobes of the lungs; and I may remind you that the converse of this is true (though with more numerous exceptions) of common inflammation of the lungs. Pneumonia affects by preference the lower lobes; it does sometimes commence in the upper, but that is comparatively rare. When it occupies the superior lobes, it generally has arrived there by travelling upwards from the inferior. You will at once perceive the practical advantage of knowing these points of contrast.

It is a curious fact also—less practically useful, perhaps, than the former, but still a valuable fact—that the left lung is much more obnoxious to tubercular disease than the right. Modern observers have collected numerical statements showing that this really is so. Why it should be so, I know not. Thus Louis, whose volume is the result of immense labour in observing, and is full of the most instructive matter, had

met with *seven* cases in which tubercles were confined to a single lung: in *two* of the seven cases it was the right lung that was thus exclusively affected, in *five* it was the left. Of 38 instances in which the upper lobe was totally disorganized by the disease on one side, 28 were of the left, and only 10 of the right. Eight times he had known the pleura perforated by the extension of tubercular disease; and seven times out of the eight the perforation happened on the left side of the chest. So also Reynaud met with 27 cases of pneumothorax on the left side, to 13 on the right. No less curious is it that here also the facts ascertained with respect to pneumonia are just the contrary of those which belong to phthisis. I mentioned, in a former lecture, Andral's conclusion, derived from the observation and collation of 210 examples, that pneumonia is more than twice as common on the right side as on the left. M. Lombard, of Geneva, found the ratio somewhat less than this, but still great. Of 868 instances of pneumonia, 413 occurred on the right side alone, 260 on the left alone, and 195 on both sides at once. That is, there were three on the right side alone, for every two on the left alone.

The tubercular matter, then, being deposited on the inner surface of the vesicles, and of the small bronchial tubes that conduct to them—groups of these diseased air-cells, lying contiguous to each other, become, more or fewer of them, amalgamated, or fused, as it were, into one large mass: and generally there are tubercles of various sizes, from that of a pin's head, to that of a pigeon's egg, in the same lung. And there is yet another disposition which the tubercular matter is apt to take: it sometimes is diffused uniformly over a considerable space, occupying all the vesicular and interstitial portions of the part affected, and having no distinct circumscribing boundary. The part looks as if fluid tubercular matter had been poured into it, and there had hardened. This is what the French call *tubercular infiltration* of the lung.

The tubercular matter, once deposited, may remain for a longer or shorter time in what is called the crude state; surrounded by perfectly healthy lung, undergoing no increase in quantity, and no alteration of consistence. But in a vast majority of cases, scrofulous inflammation is sooner or later set up around the tubercles—or in the areolar tissue imprisoned within the agglomerated masses—and then the whole breaks down in the way I mentioned before; and the detritus is conveyed through one or more tubes into the primary divisions of the bronchi, and thence to the mouth, to be expectorated. Of course there is an excavation, cavity, cavern, or vomica, left. All these names are given to the void space which the tubercular matter previously occupied. Now there are some interesting particulars to be mentioned respecting these cavities; but I must postpone them till our next meeting.

FIG. 68.

The apex of a lung affected with tubercular pneumonia; the limitation of the disease was defined by a sharp line bounding the inflamed tissue, which surrounded the tubercular deposit.

LECTURE LVI.

Phthisis, continued. Vomica; adhesions of the pleura; ulceration of the larynx and trachea — of the intestines; fatty liver; waxy liver; auscultatory signs of a vomica; gurgling, cavernous respiration, pectoriloquy: general symptoms of phthisis; cough, expectoration, dyspnœa, pain, hectic fever, diarrhœa, wasting œdema, aphthæ.

WE were engaged, when we separated yesterday, in investigating the *morbid anatomy* of consumption. Bear in mind how and where the tubercular matter, which is the essence of that disease, is deposited in the lungs; that it occupies by preference their upper lobes, and the upper part of those lobes; invading gradually the lower lobes, from above downwards, as the disease advances. Both lungs are, commonly, affected at the same time, though in unequal degrees. Among one hundred and twenty-three instances of phthisis, Louis found that the tubercles were limited five

FIG. 69.

The apex of a lung containing numerous cavities, with tubercular deposit intervening. The large cavity, and several of the smaller ones, are lined with an adventitious membrane.

called cavities, excavations, caverns, vomicae. And I go on to consider certain points of practical interest connected with these vomicae.

In the first place, as you may see by the specimens upon the table, they vary greatly in size. They may be no bigger than, or not so big as a pea: they may be large enough to contain a pint or more of fluid. Sometimes the whole of the upper lobe is converted into a bag of this kind. These large cavities are never met with in the lower lobes. They are formed by the union of several that are smaller; so that they are often of very irregular shape, and divided, as it were, into chambers, by imperfect partitions, or by bands which cross them in various directions. Opening into the cavity, there is always one, and there are generally several, pervious *bronchial tubes*, which seem as if they had been cut off just where they enter the cavity. But you never, or very seldom indeed, find a *blood-vessel* thus opening into the cavity. And the reason of these differences is plain enough. It is not, as some modern authors have fancied, that the arterial or venous tissue possesses a low degree of vitality, and therefore resists or avoids the destruction in which the surrounding tissues are involved. That principle may be applicable to other cases, but it is not applicable to this. The opinion I am now referring to proceeds on the supposition that the bands which sometimes cross the cavities are really blood vessels that have escaped the disorganizing process. Such seems to have been the notion entertained

times to the left lung, and twice to the right. The tubercular matter, once deposited, may remain quiet and unchanged for some time; but in general it increases in quantity, until at length inflammation, of a low and serofulous character, arises in the pulmonary substance in immediate contact with the tubercles — or in the areolar tissue involved in the larger agglomerated masses — in consequence of which inflammation, a sort of suppuration takes place: the tubercular matter becomes soft, and breaks down, and is ultimately expelled through the bronchi, trachea, and mouth. The vacuities left in the lung after this process of expulsion are

by Bayle; and it has been more recently and more expressly advanced by Cruveilhier. But the truth is, that these bands rarely *contain* blood-vessels: and when they do contain them, the blood-vessels are mostly *impervious*. In one hundred and twenty-three cases, Louis found pervious blood-vessels in the bands no oftener than five times.

The true reason why bronchial tubes open into these cavities, and blood-vessels do not, is to be found in the natural differences between the two sets of vessels, in respect of their structure, and in respect of the fluids that pass through them. The blood-tubes yield readily to external pressure. Many of them are pushed aside and flattened by the progressive increase of the tubercular matter around them; some probably are obstructed by its gradual accumulation within. In either case the stagnant blood coagulates, and the vessel is obliterated to some distance from the place of the original obstacle; just as you know a clot forms, and seals up an artery, for some little way anterior to the ligature. But the bronchial tubes are neither so easily compressed, nor do they carry any coagulable fluid. In the agglomeration of the tubercular masses, by the softening of which the cavities are formed, the air-tubes included within the mass are filled up by it; and when the whole breaks down in serofulous suppuration, they are expectorated with the rest of the detritus. Meanwhile their open mouths, on the hither side of the point where the tubercular matter stopped, remain, and afford a channel through which the same matter, after it has become soft, finds its way towards the trachea. Occasionally, indeed — but that, I repeat, is a rare occurrence — a considerable blood-vessel *does* get laid open during the formation of a vomica, and then copious and fatal hæmorrhage ensues. Occasionally also an oozing of small quantities of blood takes place from the inner surface of the cavity, tinging the matter expectorated. Hæmoptysis is certainly much more frequent before the softening and expulsion of tubercular matter than afterwards.

When the vomica is first formed by the expulsion of the tubercular matter, its inner surface is soft and ragged; and if other softening tubercles are in the immediate neighbourhood, the cavity goes on enlarging; that is, two or more vomicæ coalesce. If, however, there happen to be no more tubercles thereabouts, the cavity may remain

FIG. 70.

A lung, exhibiting extensive tubercular disorganization throughout its upper lobe, which is almost converted into one rugged cavity. The pleura is very much thickened; intimate adhesion has taken place between the upper and lower lobe, and the tubercular deposit is seen encroaching upon the latter.

FIG. 71.

Pulmonary caverns intersected by cord-like bodies. From a specimen in the cabinet of Dr. Gross.

When the vomica is first formed by the expulsion of the tubercular matter, its inner surface is soft and ragged; and if other softening tubercles are in the immediate neighbourhood, the cavity goes on enlarging; that is, two or more vomicæ coalesce. If, however, there happen to be no more tubercles thereabouts, the cavity may remain

stationary. Its inner surface then becomes smoother: and something like a membrane forms upon it: and sometimes a puriform fluid is poured out by this surface, and sometimes not. Generally the pulmonary tissue around such a cavity is condensed and solidified; partly perhaps by crude tubercular matter which it contains, partly in consequence of the inflammatory process of which it has been the seat during the softening of the tubercles. It is important to bear in mind this fact of the condensed, solid state of the lung immediately surrounding a vomica; for it explains certain peculiarities met with in the symptoms.

There is another point of much interest connected with these vomicæ. When they occur singly, without other tubercles or cavities (which, though a rare thing, does sometimes happen); and when occurring thus singly they have been completely emptied of the tubercular matter; they may gradually contract, and ultimately become obliterated. This approach of their sides leads to a puckering of the pleura on the surface of the lung: and, on the other hand, a puckering of the surface indicates that beneath it there is probably a shrunken, or an *obsolete* vomica. The central part of the diseased spot is converted into a substance resembling cartilage; and the appearance it presents is called a cicatrix; and really it deserves that name. The process which has gone on is a process of natural recovery: and the recovery would be complete and permanent, if no fresh deposit of tubercular matter took place. Too often, however, the tubercles multiply, until at length their number, or size, or effects, become incompatible with the further continuance of life.

FIG. 72.

FIG. 73.

Fig. 72.—Cicatrix at the apex of a lung, resulting from the previous arrest of tubercular disease.

Fig. 73.—Internal section of the summit of the left lung, showing the stellate puckering at the apex, and another lower down. Corresponding with the former may be seen a cavity the size of an almond, in process of contraction, and surrounded by dense fibrous radii. Natural size. *From Bennett.*

This, then, is one way in which tubercular disease, *limited to one small* portion of the lung, *may* be climinated, and the part which it occupied undergo a kind of repair. But the disease, *when so limited, may* cease in another way. The more watery parts of the morbid secretion may be absorbed: and the earthy salts it contains may concrete; and the whole be converted into a shrivelled, hard, chalky mass, which sometimes is coughed up, sometimes, in favourable cases, remains for years in the lung, an inert and almost harmless body.

Let me state, while I think of it, that the expectoration of these chalk-like concretions, denoting, as it usually does, the existence of pulmonary consumption, marks at the same time the chronic character of the case. I am acquainted with a gentleman who, though delicate, enjoys a very fair share of health, and who has for years been coughing up, at intervals, little branching fragments, like bits of white coral, consisting principally of carbonate and phosphate of lime, and evidently moulded in the smaller bronchial tubes.

Take notice that depressions and puckerings on the surface of a lung do not always indicate the presence of a cicatrix, or of an obsolete tubercle, beneath them. It is obvious that they may, and in point of fact they often do, result from mere lobular collapse, or from circumscribed atrophy of a portion of the lung from any cause; the neighbouring tissue being sound, or perhaps emphysematous.

When the tubercles are numerous—or rather when they lie near to the surface of the lung, as, of course, they are likely to do when they *are* numerous—they very generally give rise to dry or adhesive pleurisy. So that, in a person dead of consumption, it is a very rare thing to find the lungs free from adhesions to the ribs. I mentioned before that this attachment of the lung to the walls of the chest affords a protection against a much more formidable condition; namely, perforation of the pulmonary pleura, and the escape of tubercular matter and air into the serous cavity: producing that worst kind of pleurisy which implies pneumothorax. That the pleurisy and adhesion are consequences of the presence and irritation of the tubercles, appears from this:—that, for the most part, the extent and the situation of the adhesions correspond with the extent and situation of the tubercular disease. Thus, a single spot of adhesion has been seen to unite the costal and pulmonary pleuræ exactly opposite a solitary tubercle which lay near the surface of the lung. As the summit and back part of the upper lobes are most thickly set with tubercles, so here also is the adhesion the most constant, and the most firm. You will often find the upper part of the lung invested with a thick cap of false membrane: and the connexion between the pleuræ so tough, that the lung breaks down in the attempt to separate them.

To show you that these statements—which have long been familiar to those much conversant with disease and with morbid anatomy—to convince you that they are strictly borne out by numerical or tabular facts, I may again have recourse to Louis. He tells us that in 112 cases which he himself examined of persons dead of consumption, and having therefore tubercles in their lungs, there was but one in which both lungs were free from adhesions. In eight cases the right lung was exempt from them; and in seven cases the left. Again, in twenty-five other instances, there were either no cavities, or very little ones; and the adhesions were accordingly of small extent, and easily broken down. In the remainder there were large vomicæ, and the adhesions were extensive, dense, and firm.

Such is a sketch of the changes which take place in the *lungs*, in consequence of the deposition of tubercular matter in them, and of the changes which that matter undergoes. But the air-passages that lead to the lungs are very liable to become implicated as the disease proceeds. The mucous membrane of the larynx and trachea ulcerate: and when the morbid condition of the larynx gives rise to prominent symptoms, and especially (as it is apt to do) to hoarseness and loss of voice, the disease is sometimes called *laryngeal phthisis*. But there is no such disease, that I know of, existing by itself. I mean, that *scrofulous* ulceration of the larynx and trachea occurs only when the lungs are affected with tubercles. It is curious that when ulcers are met with in the trachea, they are often found on one side of it only; on the side, viz., which corresponds with the diseased lung, or with that lung which is most diseased. In like manner, when some of the bronchi are found red internally, and even ulcerated, these appearances are confined to those bronchi which communicate with cavities; and do not occur in the bronchial canals leading to crude tubercles. It is towards the back part also of the trachea that the ulcers, especially when large, are most commonly observed; the floor of that channel as the patient lies supine. And when the epiglottis is involved in the mischief, the ulcers are situated, almost always, on its laryngeal surface alone. We have strong reasons therefore for believing that their formation is influenced by the contact of the matter which is expectorated, in its frequent passage over the mucous membrane. Moreover the little mucous glands

wherewith the membrane is provided, are most numerous at the posterior part of the trachea and bronchi; and these glands are especially prone to ulcerate.

In respect to these points also Louis has made comparative observations. Among 180 persons who died of some chronic disorder, *not* phthisical, he once only met with ulceration of the larynx; whereas of those who perished of consumption, about *one in every five* had ulceration of the epiglottis or larynx, and nearly *one in three* had ulceration of the windpipe. Hence it would appear that, if we except the effects of the syphilitic poison upon the larynx, ulceration of that part is almost peculiar to phthisis pulmonalis.

I have told you that consumption is not merely a lung disease. Its local ravages are most obvious indeed in the thorax; but it leaves in the abdomen also traces of its destructive agency not less definite, and scarcely less constant. You know that the surface of the intestinal canal is strewed, throughout, with separate mucous follicles; and that the lower portion of the ileum is furnished with other follicles, collected together in oval or circular groups. When I come to speak of continued fever I shall have much to say about the changes which these little glandular bodies undergo, in one form at least of that disease. These same glands are the frequent seat of tubercular deposit in phthisis. Here and there you may see a solitary yellow tumour, not larger than a hemp-seed, projecting from the surface of the bowel. In other places the ripened little tumour has burst, the tubercular matter is gone, and a ragged roundish ulcer remains. More frequently the aggregated glands are affected; and the ulceration, in them, varies much in form and extent. It often involves the whole patch, and then the shape of the ulcer is more or less elliptical. Louis met with ulceration of these glandulæ agminatæ in five-sixths of all the fatal cases of phthisis that he examined. Ulcers of greater magnitude, were very nearly as common in the large intestines. And it is worthy of notice that, the disorganizing process being in these cases slow, nature has time (if I may use such metaphorical language) to provide against the threatened perforation of the gut. The tissue that forms the base of the ulcer, whether it be the muscular or the peritoneal coat, is thickened and vamped; or the bowel becomes adherent to some contiguous surface. Once only in my life have I known scrofulous ulceration, in phthisis, penetrate the serous tunic, and allow the contents of the intestine to escape into the sac of the peritoneum.

You ought to be aware — although the facts possess, as yet, no practical value — that the stomach is often much enlarged and thinned in those who die of consumption; and that the liver is very apt to undergo remarkable changes, almost yet not altogether peculiar, I believe, to that disease. It, too, enlarges, and there are two varieties of its enlargement. In the first, the liver becomes full of adipous matter, greasing the hands and scalpel of the anatomist, and yielding when heated an oily substance, which makes a grease-spot on paper placed in contact with it. The whole gland partakes in the alteration, is of soft consistence, loses its natural red tint, and assumes a pale fawn colour. In three years Louis met with this fatty liver, as it is called, forty-nine times; and forty-seven of the patients died phthisical. It occurred in one-third of the whole number of the victims to consumption; whereas, among two hundred and twenty-three cases, not phthisical, there were two examples only of this hepatic change. It is more common in women than in men.

The second kind of enlargement is produced by the infiltration of the hepatic tissue with an albuminous material. The cut surface of a liver thus altered has a whitish and glistening appearance; hence it is called the *waxy* liver; and by the Germans, from its resemblance to bacon, the *lardaceous* liver. The waxy liver so far resembles the fatty, that it is frequently observed in connexion with scrofulous disease; and that it is large, sometimes exceedingly large, with a smooth surface, and a blunt lower edge. Both these forms of hepatic enlargement proceed insidiously, with little or no pain or tenderness. Their presence is revealed during life by no symptoms, except that the enlargement belonging to them may at length be ascertained by percussion and pressure with the fingers.

Let us now inquire what modifications of the healthy sounds arise from the altered conditions of the lungs in phthisis. Most of them are such as you would naturally expect. Whether a portion of lung be rendered solid by common inflammation, or by the presence of tubercles in it, the result, so far as the auscultatory signs are concerned, will be the same. In such a piece of lung, supposing the solidification com-

plete, no vesicular breathing can be heard; but bronchial breathing and bronchopony will be audible, in each case, if the solidified portion enclose a considerable bronchus, and come near the surface of the chest. And percussion will give a dull sound, whether the lung lying beneath the part struck be hepatized, or blocked up by tubercular matter. On these points, therefore, after what was said in a preceding lecture, I need not dwell. But the excavations—the empty or half-empty vomicæ—these are something new. We have hitherto met with no condition exactly similar to that of a large cavity. And accordingly I have to make you acquainted with two or three new sounds: or sounds which are modifications of those formerly described, and in most instances sufficiently distinct from them to have acquired peculiar names. You will remember that what we have called large crepitation depends upon the passage of air through liquids; the liquids being contained in tubes; those tubes the bronchi and their ramifications. But when pus or vitiated mucus, or liquid of any kind, is collected in a *vomica*, which communicates freely with the trachea through pervious bronchi, the bubbles produced by the entrance and exit of air will be still more numerous and large; and a sound is then produced which the word *gurgling* expresses well. Laennec calls it *gargouillement*. This sound is heard, too, in a circumscribed space; and not diffused, as large crepitation usually is. Wherever, therefore, we hear gurgling during respiration, or during the act of coughing, there, we conclude, exists a *cavity*. But the cavity is not necessarily a *vomica*. In ninety-nine cases out of a hundred it will be so; but in the hundredth case perhaps it will not. Bear in mind what was formerly stated of dilatation of the bronchi: how sometimes they terminate in a considerable globular expansion; sometimes belly out and contract again several times alternately: and you will see that cavities containing liquid, or liable to contain liquid, belonging equally to the one condition and to the other, and the sound in question depending solely on the intermixture and agitation of air with liquid in a cavity, we cannot be sure from mere gurgling respiration, or gurgling cough, that we have a *tubercular* excavation beneath our ear; or that the case is one of consumption. Gurgling may also proceed from that very rare morbid condition, abscess, the result of common inflammation of the lung. These constitute the only sources of fallacy in the matter. The fallacy seldom interposes; but it does sometimes interpose; and therefore it must *qualify* our conclusion from this symptom of gurgling, with respect to cases otherwise doubtful.

Again, the vomica may be empty of liquid; and then we hear, as the patient respire, not vesicular breathing of course, nor yet exactly bronchial breathing; it is something more than that when the cavity is large, something different in character from it when the cavity is small: but whatever the character of the sound, as we believe it to take place in a vomica or cavern, we call it *cavernous respiration*. It is a hollow sound, especially when the cavity is of considerable size; an exaggeration of mere bronchial respiration. But the cavity may be small. The moment a portion of tubercular matter is separated and discharged through a neighbouring bronchial tube, the cavity has commenced; and the sound produced in these little cavities during the breathing may be of various kinds. It may be, and it often is, a click, like the opening and shutting of a valve; or a chirp; or a creaking; or like many other well-known sounds; but, as all these sounds, under certain circumstances, denote the formation of a vomica, it is best, for simplicity's sake, to call them all by the same name—*cavernous respiration*.

Dr. Latham explains in a few words the causes of these differences. "The varieties of cavernous breathing are doubtless owing to different sizes, and forms, and situations of cavities, and to different conditions of the surrounding lung. A cavity may be very large or very small. Several bronchi may open into it, or only one. It may be a simple cavity, or it may have many chambers. Its sides may be condensed and equal, or rough and ragged. The lung around it may be solid and indurated, or pervious and vesicular. It may be near the ribs, or far from them: adherent to, or separate from the pleura. It is quite obvious that these different circumstances are calculated to modify the sound, which will, nevertheless, be always such as indicates a cavity."

A tubercular cavity may be so large, and of such a kind, as to yield the metallic sounds which are apt to be heard in pneumothorax. I show you a cavity in which those sounds were actually heard, most distinctly, by many persons, during the

patient's life, while he was under my care in the Middlesex Hospital. I was certain beforehand that these sounds proceeded, not from the cavity of the pleura, but from a tubercular excavation. Once subsequently, in a patient who was dying of phthisis and diabetes, I have heard the same sounds; also, I am sure, in a tubercular cavity. The patient insisted on leaving the hospital, and I lost sight of him before he died.

I promised, when speaking of these metallic sounds as arising (as they much more commonly do) from pneumothorax—a collection of air, or of air and a liquid together, in the sac of the pleura—I promised to point out the circumstances whereby you may tell which of the two conditions in question the sounds denote. Both of the conditions imply, in general, the existence of tubercular phthisis; and therefore the observation of the ordinary symptoms of phthisis will not help us much.

Now, in the cases seen by me, there were two circumstances that stamped them as being cases in which the sound proceeded from a cavity in the lung, and not exterior to it. One was the *situation* in which the sound was *invariably* heard. The other was, the absence of excessive resonance when that part was percussed. You know that when air is contained in the pleura itself, the sound yielded on percussing the chest in the corresponding spot is quite tympanitic, like that of a drum. But it is a well-ascertained fact, (though contrary perhaps to what you would suppose,) that the sound is duller over tubercular cavities, in nine cases out of ten, than over sound lung. The explanation of this fact is simple enough. It is that the layer of lung which still remains in such cases, thick or thin, is dense and solid, and damps the sound which the vomica might otherwise make resonant. But then again the situation of the metallic sounds was a guide. They occupied the upper part of the chest: the very part where vomicæ are wont to be the most common, and the largest: and moreover a part where pneumothorax seldom or never exists. The summit of the lung is generally covered in phthisis with a cap of false membrane, which binds it to the ribs: and this, as I observed before, is the main reason why perforation of the pleura pulmonalis is so rare in that disease; and it is also the reason why, when it does take place, it seldom takes place at or near the apex of the lung. In truth it is found by experience that (though the rupture of the pleura *may* happen in any part) the place where it usually occurs is in the lower and back part of the upper lobe of the lung, opposite the angle of the third or fourth rib; that is, just beneath the edge of the false membrane by which the summit of the lung is generally adherent. But the sound, in the cases I refer to, was *invariably* heard at the very top of the chest. It did not shift, as that of pneumothorax may often be made to shift, when the patient changed his posture. Attention to these points will always lead you to an exact diagnosis. You may say, perhaps, "The complaint being in each case a mortal one, what is the use of so much refinement?" Why, there is this utility in it. We may sometimes, as I stated before, give great relief to the patient, and save his life for a time, by tapping the chest in pneumothorax. Air may get in with each inspiration, and threaten immediate suffocation; and the thorax being punctured, it will issue in a blast. But no one would think of tapping a tubercular cavity.¹

To give out the amphoric resonance and the metallic sounds, the vomica must, I presume, be a *large* one. That which is before you, the only one I ever *saw* in which those sounds had been heard, is very large. Its inner surface is smooth: it adheres to the ribs externally by at least two-thirds of its circumference: and the medium of adhesion is very thin. Quite low down, a single bronchial tube, of about the third division, may be seen to enter it.

So much, then, for the modification, by a tubercular cavity, of the sounds heard during *respiration*. But the *voice* will also be modified, if the cavity be of considerable size, and near the surface, and have dense walls, and be empty. Then we hear, in that part, when the patient speaks, the sound which is called *pectoriloquy*: as if the voice proceeded from the chest. The words are distinctly articulated into the ear of the listener. But I need not trouble myself or you by attempting to *describe* pectoriloquy. You may any day hear the exact sound that word is intended to denote, by placing a stethoscope over the trachea of one of your friends, applying your ear to

¹ In this the author finds that he was mistaken. The operation has since been proposed and practised. That it can meet with much success, or favour, he does not yet believe.

the other end of it, and getting him to speak : just as you may obtain an exact notion of bronchial respiration by listening then to his breathing.

For some time after the first appearance of Laennec's great and original work on the diseases of the chest, pectoriloquy was deemed to be the pathognomonic and infallible sign of a vomica. "Oh," the young auscultator would say, "I detect pectoriloquy beneath the clavicle. There can be no further doubt about the nature of the disease. My patient has not only tubercles, but a cavity in his lung." So I long thought; and so some, I fancy, think still. Yet the evidence afforded by mere pectoriloquy of the presence of a vomica, or even of the presence of tubercles, is far from being certain or trustworthy. Experience had taught me this before I knew that many others, studying under the same schoolmaster, had learned the same truth. Among my hospital patients many years ago was a man who laboured under phthisis. Percussion gave a dull sound under his right collar-bone, and in the same spot loud and distinct pectoriloquy was audible. I well recollect inviting the particular attention of the pupils to this case, as affording an exquisite specimen of pectoriloquy; and I predicted very confidently that after the patient's death, which was obviously at hand, a large excavation would be found in the summit of his right lung. My prediction did me no credit. The *left* lung indeed was hollowed by cavities, but there was nothing like a cavity in the right. The upper part of the lung was thoroughly and uniformly solid; filled with hard, grey, tubercular matter. The large bronchial tubes were pervious, and the voice descending into them had been conducted by the solid lung with perfect and almost painful distinctness to the listener's ear. This was a useful lesson to me: and I mention it that it may be a lesson to you. Remember that solidification of the summit of the lung will modify the sound of the patient's voice, very much in the same manner as a large vomica there situated. It is stated, indeed, and perhaps truly, that a practised ear can discriminate between the loud, diffused, though articulate, resonance of the voice produced by solid lung, and the circumscribed, whiffing pectoriloquy of a cavity. But the distinction is too nice for the average of ears. Now since the pulmonary tissue may be rendered dense and solid by other causes than tubercles, pectoriloquy does not always indicate the existence of consumption. The fallacious condition does not often occur; for common inflammation is seldom limited to the upper part of the lung; and the whole of that part is seldom completely hardened by crude tubercles. But whenever it does occur, it is apt to mislead or puzzle. I was consulted last year about a gentleman in whom this phenomenon of pectoriloquy was strongly marked. Two excellent auscultators had been led, by this symptom, to the belief that a cavity existed in the lung. Remembering the case I have just mentioned, and learning that the patient had been ill for a few days only, and had not previously suffered enough, nor any apparent pectoral complaint, I was of opinion that the summit of his right lung had become hepatized by acute pneumonia. And it was so. The patient died; and the diagnosis I had formed was verified upon inspection of the lung. Dr. Latham relates one or two examples to the same purpose. Dr. Stokes goes so far as to consider pectoriloquy the least important and most fallacious of all the physical signs of phthisis. Taken alone (he says) it is absolutely without value. Sir John Forbes has come to similar conclusions. Certainly cavernous respiration is a much more alarming sound.

Wherever actual pectoriloquy from a cavity is heard, there also will be heard cavernous respiration. But the converse of this is not necessarily true. There may be, and there often is, cavernous respiration and a cavity, yet no pectoriloquy. The cavity is not large enough, or not near enough to the surface of the chest, or not of such a kind as to reverberate the voice.

Often when pectoriloquy is absent, and cavernous respiration is doubtful, and gurgling even cannot be heard (because the communication with the bronchi is not free), a slight splashing sound will occur when the patient coughs: nay, you may sometimes hear it, if he hold his breath, with every beat of his heart, which causes a little succussion in the cavity: but its contents must then be thin.

Now when the sounds I have been engaged in describing are well marked, they denote the existence of a vomica. The only source of fallacy is that which I formerly mentioned; the same sounds may arise from a cavity in the lung, whatever be its nature; and therefore they may arise when the bronchi are expanded into cavities.

But I repeat, that this is a deceptive condition which you cannot calculate upon meeting with often.

When the sounds are not well marked, take time before you pronounce a decided opinion respecting them. Strong bronchophony comes very near to weak pectoriloquy: bronchial respiration may closely resemble some varieties of cavernous breathing: large crepitation, confined to a small spot, may simulate gurgling. It is better, when the sounds are thus equivocal, and when they may denote conditions so very different in their nature and tendency, to suspend one's judgment, and to give a guarded opinion. A little time in such cases will clear away the doubt.

I am afraid of being tedious about these sounds; but really they are of immense importance. Upon their exact appreciation, and correct interpretation, will depend the opinion you will be *called upon* to express; and that opinion will, in many cases, be a sentence of life or death with respect to the dearest friends of those who hear it. A correct diagnosis is also very important, in the early periods of the disease especially, for another reason. It is in those early periods alone that we can entertain much hope of arresting the progress of the complaint by art, or by change of climate.

I must now consider the *general* symptoms of this most afflicting disease: and while doing so, I shall point out how the physical signs confirm or confute their language, in cases which might otherwise be doubtful.

The general symptoms of phthisis are cough, dyspnoea, expectoration, hæmoptysis, wasting, hectic fever, hoarseness or loss of voice, diarrhoea; and there are some other symptoms which mark often some of its stages, and to which I shall incidentally advert. I shall speak of them all as briefly as is consistent with clearness.

Cough is one of the earliest symptoms of consumption; and it is that which commonly first attracts the attention, and awakens the fears, of the patient or the patient's friends. Generally at first it is slight, occasional, and dry: it occurs upon the patient's getting out of bed in the morning; or if he make any unusual exertion in the course of the day. It feels to him as if it were caused by irritation about his throat. Sometimes it will cease for a while, as in the warm weather of summer, and recur in winter when the external temperature is lower. By degrees it begins to be troublesome in the night: and to be attended with more or less expectoration of mucus.

Now when such a cough steals upon a person gradually, and when no reason can be assigned for its occurring, that circumstance alone is enough to excite suspicion as to its true nature and cause. But chronic cough may exist without any tubercular disease of the lungs: as you well know. It may depend upon a disordered state of the *stomach*; the *pneumogastric* nerve may be irritated *there*. It may be the cough of *chronic catarrh*; it may result from disease of the *heart*; it may be the nervous, barking, importunate cough which I formerly mentioned as of frequent occurrence in *hysterical* girls. And bearing these circumstances in your mind, you will inquire, and you will generally make out without much difficulty, whether there be any unnatural or deranged state of the digestive organs; or chronic catarrh; or cardiac disease; or hysteria. These are points on which I need not further insist.

I may observe, here, that as chronic cough may exist when there is no consumption; so consumption may sometimes exist, and even prove fatal, and large portions of the lungs may be disorganized, without there having been any cough; or at least without the occurrence of enough cough to draw the notice of the patient or of his friends to it. This is not common, however: cough is usually present, more or less, during all the stages of phthisis, and it is often that symptom which most distresses and harasses both the patient and his family.

Great attention used to be paid to the *expectoration* in cases of suspected phthisis. It was thought that if a patient spat pus, he was in a state of confirmed consumption: and whole volumes have been written, and prizes awarded to their authors, respecting the means of distinguishing pus from mucus. But we now know that, so far as the diagnosis of phthisis is concerned, this is a very idle inquiry. The inflamed bronchial membrane may secrete pus; so that the presence or absence of pus in the sputa is no test at all of the presence or absence of tubercles in the lungs. If you are, nevertheless, curious to know how pus may be identified, one easy criterion is that proposed by the late Dr. Young. You are aware that pus, like the blood, con-

tains globules; and these globules, when examined through transmitted light, exhibit prismatic colours; appear surrounded by rings of colours, somewhat resembling those of the rainbow, but differently arranged, and often beautifully brilliant. Mucus, having no such globules, affords no such coloured rings. The way to make the examination is, to put a minute quantity of the fluid between two small pieces of plate glass; to hold the glass close to the eye; and to look through it at a distant candle, having a dark object behind it. A yet readier, and I believe a better test, is furnished by the *Liquor Potassæ*, which converts pus into a viscid stringy mass, while it liquefies mucus.

For those who possess, or have access to, a good microscope, all other means of discrimination become superfluous. The globules peculiar to pus may be recognised, by an instructed eye, at a moment's inspection.

Whether the expectoration be puriform or not, has ceased, however, to be a question of much importance as regards the diagnosis of phthisis. A portion of the matter expectorated comes from the surface of the bronchi, and consists of altered mucus: and therefore, the sputa brought up in phthisis, and the sputa brought up in bronchitis, are, in a great degree, the same. These are partly composed of a ropy transparent fluid, in which opaque masses of a yellow or greenish colour are seen to float; and intermixed also with which there may be a good deal of froth. The froth is a measure of the difficulty with which the mucus is brought up: and it is usually less abundant and conspicuous in phthisis than in bronchitis. The heavy, sage-leaf sputa that we sometimes see, belong to both diseases.

You may occasionally find portions of tubercular matter in the expectoration; a circumstance quite decisive, when we are sure of it, of the nature of the case: dull yellow streaks, or little eurd-like fragments involved in the mucus. But small opaque specks of that character are sometimes formed in the follicles of the tonsils; and this makes the appearance more equivocal. The sputa *most* characteristic of tubercular disease consist of globular, grey, flocculent masses, which look like little portions of wool more than anything else. *Nummular* sputa the French call these, because when spat into a vessel not containing water, they assume a flat circular form, like a piece of money, and remain separate and distinct from each other. When they are spat into a glass of water, you perceive that some of them subside to the bottom—some float on the top, suspended, apparently, by healthier mucus in which they are entangled, or by bubbles of air—and some remain stationary at different depths. When stirred and agitated in the water, they render it slightly milky. This kind of expectoration commonly marks a confirmed and advanced state of the disease; but it will continue for weeks sometimes. It is not *perfectly* pathognomonic, but *nearly* so. On one occasion I found expectoration of this nature from a man whom I did not very diligently examine by my ear; and I set the case down as one of phthisis chiefly on the observation of that symptom. The patient evidently had not long to live. Our apothecary at the hospital, Dr. Corfe, had more time to explore the condition of the chest: and he came to the conclusion that the disease was not tubercular phthisis, but extensive chronic bronchitis: and sure enough he was right. When we came to examine the lungs after the patient's death, not a tubercle could be found. I am satisfied that there is no kind of expectoration which indicates phthisis with *perfect* certainty: but that which I have just been describing very *seldom* occurs unless there is phthisis. Louis appears to have noticed these round, separated, woolly masses twice only unconnected with tubercles: and once the same thing has occurred to Chomel: so that, when the other symptoms are obscure and doubtful, this will materially augment the gravity of the prognosis. Flies appear to be more attracted by the sputa of phthisis than by any other sputa.

Practised microscopic observers are sometimes able, I believe, to discriminate "tubercular corpuscles," and portions of broken down pulmonary tissue, in the expectoration of phthisical patients. In this method of diagnosis I must confess that I am inexpert.

Hæmoptysis is a kind of expectoration; the expectoration of *blood*. I have already spoken of this symptom as connected with phthisis, and have stated my belief on that subject; viz., that if a person spit blood who has received no injury of the chest, in whom the uterine functions are healthy and right, and who has no disease of the heart, the odds that there are tubercles in the lungs of that person are fearfully high.

Excluding cases of amenorrhœa, and of mechanical injury to the thorax, Louis did not meet with a single example of hæmoptysis among twelve hundred patients, except in such as were phthisical.

I touched at the same time upon the question, whether hæmoptysis, which sometimes precedes for a while the manifestation of any other symptoms of consumption, is ever really the *cause* of it, as the old authors maintained. You will understand my persuasion to be that, occurring in connexion with tubercles, pulmonary hæmorrhage is always the *consequence*, and never the *cause*, of their presence in the lung. Andral relates a curious case, from which the contrary opinion might be argued. "A man, ill of chronic peritonitis, had been for nearly two months in La Charité, and had never presented any morbid symptom which had relation to the organs of respiration. He had no cough, and he breathed easily. One evening, for the first time, he suffered some dyspnœa; and in the course of that night he spat up a large quantity of florid and frothy blood. For the five following days the hæmoptysis continued abundant, then it diminished by degrees, and at length stopped. But the patient continued to cough, and to breathe with difficulty, and at length he died. In the right lung there were found several masses of a brownish red colour, exactly circumscribed, and constituting, in short, that condition which Laennec has called 'pulmonary apoplexy.' One of these masses contained a considerable number of granulations of a yellowish white colour, and having all the characters of minute tubercles in an early state. Two others of the red masses contained each a very small number of these white granules; and in the remaining masses no tubercles at all could be discovered, nor was there any trace of them in other parts of the lungs; but they were numerous in the false membranes of the peritoneum."

Andral argues, that in this case the partial collections of blood that were found in the lung could not have been *occasioned* by the presence of tubercles, because in the majority of these masses no traces of tubercular matter could be perceived. On the other hand, their existence appears *connected* with that of the apoplectic masses, because, except in the midst of some of these, no pulmonary tubercles could be seen. But such a case as this hardly bears out the conclusion that pulmonary hæmorrhage is ever the cause of tubercles. There were tubercles in the abdomen before; therefore, the disposition to tubercular disease pre-existed in this individual; and then tubercular matter was deposited in the places where blood was extravasated; just as we know it is deposited in the blood itself, in the spleen sometimes; or, what I think more probable still, the cluster of granulations provoked the hæmorrhage from the spot they occupied, and other lobules of the same lung became blocked up by the reflux of blood, in the manner formerly explained.

Prior to the age of fifteen, hæmoptysis, even in phthisical children, is extremely uncommon.

Dyspnœa is not a very important symptom in phthisis. It is seldom extreme till towards the termination of the disease, and not always then. Patients who fear, and yet are unwilling to believe, that they are consumptive, will fetch a deep breath, and bid you remark how thoroughly they can distend their lungs; and they expect you to say that there can be no disease in those organs. I have been told that the late Dr. Baillie died of pulmonary phthisis; and that even he was accustomed to delude himself by this test. However, if phthisical persons do not in general suffer much from dyspnœa, their breathing, although they may not be aware of it, or may not choose to acknowledge it, is generally, in some degree or other, short, or hurried. You may wonder that a disorder in which so large a portion of the breathing apparatus is so often effectually spoiled, should be attended by so little distress in respiration; so little dyspnœa: but your surprise will be diminished if you consider the insufficient manner in which consumptive patients are nourished, in consequence of abdominal disease; and the extent to which their blood is wasted by diarrhœa, and by perspiration. The mass of blood is thus kept down to that measure which, passing through the still pervious portions of the lungs, is capable of being arterialized without any great deviation from the ordinary mode and frequency of breathing.

Neither is *pain* of the chest a very important symptom in consumption. In some cases severe pains are complained of, resembling those of rheumatism; in the sides, or beneath the clavicles. In others, no pain at all is experienced. When sharp pain

occurs, it may be supposed that the pleura is inflamed and beginning to adhere in the painful part.

There is, however, one contingency of which the two symptoms last mentioned are sometimes very significant. When, during the progress of phthisis, violent pain of the side, and extreme dyspnoea and anxiety, set in *suddenly*, they denote, with much certainty, perforation of the pleura, and its serious consequences.

The *hectic fever* which accompanies phthisis is of much greater moment. It often creeps upon the patient insidiously. He feels chilly perhaps, towards evening; and in the night his hands and feet are dry and burning; and in the morning he perspires. The most marked symptoms of the hectic are to be found in the perspiration, and in the state of the pulse. The perspiration is usually out of all proportion to the previous chilliness and dry heat. It seems to have a close connexion with the *sleep* of the patient: it seldom comes on while he continues to be awake; but after sleeping he wakes, and finds that he is sweating. The perspiration is generally most copious on the upper part of the body, the chest and head. Sometimes it is moderate; sometimes the patient is drenched and drowned in it. There is a good deal of uncertainty about this symptom, and of obscurity as to its cause. Generally speaking, it belongs to the more advanced stages of phthisis; but occasionally it accompanies its early periods. It will cease without any apparent cause: and recur again with the same capriciousness. A poor friend of mine, who died of phthisis, and was particularly harassed by the nocturnal perspirations, took it into his head that *posture* had something to do with them; and slept for several nights in succession *sitting* in an easy chair: and during those nights he certainly did not sweat, though he had been doing so, profusely, before. Louis found that one patient in ten escaped this symptom.

This is a symptom which is often very distressing to the patient, making him even dread to go to sleep; it tends also to the rapid exhaustion of his strength; and betokens, it is believed, when copious or persistent, a short duration of the disease.

Frequency of *pulse* is a symptom so generally present in tubercular phthisis, that too much importance has been ascribed to it as a diagnostic sign. I mean, it has been too much the opinion that the lungs are safe, when the pulse does not rise above its natural standard. Sometimes it remains steady to that standard nearly up to the period of dissolution. Such cases are, I believe, generally slow in their progress. Very recently I lost a friend whose lungs were full of cavities and crude tubercles. He had been a valetudinarian for years; but the pulmonary disorder had been manifested by decided symptoms during a few months only. At no period did his pulse exceed sixty-eight beats in the minute. Commonly, however, the pulse is continually above ninety; and often it is much higher. When there is nothing to account for this increased frequency of pulse it is a suspicious symptom.

Diarrhœa is a common and an ugly symptom in phthisis. When it occurs early, as it sometimes does; when a patient having habitually costive bowels, becomes habitually relaxed; and you *suspect* only, from other causes, that he may have incipient phthisis; this change often sets its seal upon the nature of his disorder. Usually, however, diarrhœa does not become urgent until the disease is far advanced, and has already declared itself by other and unequivocal symptoms. When it so occurs, it is apt to harass the patient exceedingly; and rapidly to waste his strength and flesh. He appears to melt away under the influence of the purging; which is therefore said to be *colliquative*. It used to be held that the diarrhœa and the perspiration bore an inverse ratio to each other: that when one of them abated, the other always increased. But the more exact observations of Louis and of others have proved that this is not so: that neither in phthisis, nor in other diseases, have these symptoms any such regular reciprocal relation. One reason, perhaps, for this error, may be found in the circumstance, that acids, which have the effect often of checking the perspiration, tend also, in some persons, to produce diarrhœa. Louis found that this symptom began early in the disease, and continued through its whole course, in one out of every eight patients; and in one case only in every twenty-two was it wholly wanting. It depends most commonly, if not always, upon serofulous ulceration in the small intestines and in the colon. In Louis' experience, there were, invariably, *large* ulcers, whenever the diarrhœa had been chronic and abiding, and the stools had been numerous. In the small intestines the ulceration evidently commences in the mucous follicles; the glandulæ solitariae, or the glandulæ agminatæ; and sometimes, though not often, the ulcer perforates the bowel. It is probable that in the large intestine ulceration begins

in the same way, by the deposit of tubercular matter (which is subsequently removed) in the solitary glands: but when once begun, the ulcerating process extends itself indefinitely to the surrounding mucous membrane.

I should have stated before that, with this disease of the intestinal canal, there is often found enlargement of the corresponding glands of the mesentery, which are frequently filled also with tubercular matter.

Several of the symptoms that I have been mentioning — the state of the digestive organs, which interferes with the due assimilation of the food; the drain implied in the profuse sweats, and in the habitual diarrhoea; — conduce to cause another constant accompaniment of progressive phthisis: and that is *emaciation*. You know that the wasting in this complaint, when it is not cut short by some accidental complication before it has reached what may be called its natural termination, is extreme. It often is one of the earliest, as it is one of the most alarming, of the symptoms which the patient presents: and it frequently becomes excessive before any perspiration or purging have occurred to account for it. If, without any apparent cause, a person grow thin and weak, and his pulse be quick, and his breath at all short — these are intimations which seldom prove unfaithful, that tubercular disease is at work in the lungs, and in the abdomen.

Œdema of the ankles, and even some puffiness of the hands and face, are circumstances which seldom fail to appear in pulmonary consumption: but they are among the latest of the symptoms. *Œdema* does not tell us what the disease is in such cases. We have been satisfied as to that some time before. But (unless there is some marked disease of the heart) it tells us that the disease is about to terminate. It is worth attention as a prognostic symptom merely.

And the same may be said of aphthæ. This is one of the last of the symptoms: but in some cases it does not happen at all. I have lately described this morbid condition of the mucous membrane of the mouth and tongue, and have nothing more to say of it at present. It bears the same relation to phthisis as to other chronic disorders: and marks, for the most part, the approach of their fatal termination.

It is always interesting to couple changes of structure with their appropriate signs. I will therefore take this opportunity of telling you what Louis has observed of this relation, in respect to the larynx and windpipe.

Ulceration of the epiglottis was often latent; gave no appreciable signal of its existence. The symptoms that belong to it are, a raw, or pricking, or burning sensation, at the upper part of the thyreoid cartilage, with occasional dysphagia, and the rejection of liquids through the nose, while the tonsils and pharynx present no visible alteration.

Ulceration of the interior of the larynx is marked, when slight, by trivial pain in that part, and some variation from the natural voice; when deep, by severer pain, and abiding aphonia.

Ulceration of the trachea is seldom revealed by any symptom. And this is worth remembering; for patients are continually persuaded by medical men who know no better, that their symptoms are all *tracheal*.

There are still a few other circumstances which, when they occur, accumulate conviction as to the nature of the disorder. The catamenia are suspended in women: and the hair falls off. There are certain physical peculiarities too, which are strongly indicative of a tendency to consumption; or perhaps I should say of the scrofulous diathesis. Largeness of the pupil, with a sluggish iris — in other words, a not very sensible retina — constitutes one of these. A clubbed state of the ends of the fingers, with convex and adunque nails, forms another. Yet this last is not peculiar to tubercular consumption. I have heard of one case in which it was strongly marked: the patient died after a long illness — chronic puriform discharge from the pleura after paracentesis thoracis: but there were no tubercles. And I have recently (1857) been consulted by a gentleman whose right chest I found flattened and much contracted, and marked at its lower part in front by the scar of a puncture through which matter was discharged four or five years ago. He was still coughing up thick and puriform mucus. The ends of his fingers were remarkably bulbous, and their nails very convex. They had naturally (he assured me) been delicate and taper: and he had watched the change in their shape, which commenced with the commencement of his chest symptoms. This peculiarity seems therefore a sign of present disease, rather than of a diathesis.

LECTURE LVII.

Phthisis, continued. Diagnosis. Forms and varieties of Phthisis. Ordinary duration. Age at which it is most frequently fatal. Influence of sex; and of occupation. Question of Contagion. Treatment.

IN a former lecture, the twelfth of this course, I entered somewhat fully into the *pathology* of serofulous and tubercular diseases in general. I pointed out the fact, that though such diseases affect vast numbers of persons, and are most extensively fatal, yet that they affect almost exclusively certain *classes* of persons. That while some are so prone to tubercular disease, as to fall into it upon the operation of the slightest external causes, or even spontaneously—nay, in spite of every care to the contrary—others again, who are constantly exposed to influences likely to call serofulous disease into action, either do not suffer therefrom; or if they do become serofulous, it is only when the external circumstances most favourable to the production of such disease have been intense in degree, and protracted in their application.

At the same time I showed you how commonly the *disposition* to serofula descends in families: and I told you what observation has collected in respect to the *causes* which may *excite* serofulous disease in persons *hereditarily disposed* to it. I shall not, therefore, go over that ground again. What I then said of serofulous disease in general is true of tubercular consumption in particular. I will merely remind you that these exciting causes are essentially causes of *debility*. Whatever tends to depress the vital powers, and permanently to weaken the body, tends also, in a predisposed frame, to engender or to call forth this fearful and most destructive malady.

With respect to the detection of tubercular disease in the lungs, it is sometimes very easy, sometimes extremely difficult. It is easy when the tubercles are numerous, large, or far advanced: difficult, sometimes, when they are crude, scanty in number, and thinly scattered, and individually small. In the latter case they may not cause any appreciable deviation from the natural resonance of the chest on percussion, or from the natural smooth, equable rustle of the breathing. It would be tedious to travel over again all the auscultatory and other symptoms, with the view of pointing out their bearing upon the diagnosis. I touched upon that point incidentally, when discussing the individual symptoms, in the last lecture. Many of the symptoms tell their story so plainly that any attempt to expound or interpret them would be quite superfluous. One or two cardinal points, however, which have rather been hinted at before than expressed, I may just advert to.

The fact that tubercles occupy the *upper part* of the lung by preference, is of great moment in relation to the diagnosis. When the symptoms are equivocal; when, so far as *they* are concerned, the case may either be one of chronic bronchitis, or of tubercular consumption; a careful examination of the superior regions of the chest will often decide the anxious question. The sound resulting from the first gentle tap upon or beneath the clavicle, often rings in the physician's ear the knell of his unfortunate patient. Even unusual distinctness of the sound of expiration, if heard at the summit of the lung, and *à fortiori* if at the summit of one lung only, warrants the terrible suspicion that tubercles are breeding in that lung. It may, indeed, be laid down as a rule, which very few exceptions diversify, that if you find dulness on percussion; or indistinct breathing; or coarse inspiration; or loud and prolonged expiration; or undue resonance of the voice; or a click or morbid noise of some sort when the patient respires, or speaks, or coughs; if you find this day after day, and always between the clavicle and the mamma in front, or between the clavicle and upper edge of the scapula, over the top of the shoulder, and nowhere else; and more especially if those deviations from the healthy sounds be limited to one side, or greater on one side than on the other, or different in quality on the two sides; you may set the case down as a case of tubercular phthisis. On the other hand, if in the same parts you still distinguish all the natural sounds of respiration, and can still obtain a clear sound on percussion, you are not to condemn the case, nor to despair of recovery, whatever

its other circumstances may be. The worst symptom certainly, when auscultatory signs are wanting, is hæmoptysis.

Incipient consumption is most liable to be confounded with chronic bronchitis. Yet the leading features of the two are well contrasted. The morbid sounds belonging to chronic bronchitis are chiefly audible in the lower lobes of the lungs: those of phthisis in the upper. Some degree of expectoration attends the cough of bronchitis from the first: the cough of phthisis is often, for a long while, dry. Simple bronchitis is not accompanied by hæmoptysis. The pain that occurs in bronchitis is felt beneath the sternum: in phthisis pain most commonly affects the sides, and the space between the shoulders. It is enough, I trust, to have drawn your attention to these points, without dwelling upon them longer.

Dr. Latham, in the little work which I have several times referred to, has laid down certain distinctions most deserving of your notice, with respect to the various forms of phthisis. This portion of his book is quite original. The facts indeed have long been known: but they have never before, that I am aware of, been made so instructive, by being clearly disposed, and exhibited in their proper bearings.

He first divides phthisis generally into two forms, which he calls *mixed* phthisis and *unmixed* phthisis. And he illustrates what he means by those terms very simply and skilfully. He takes the case of an absorbent gland in the neck, affected with serofulous disease. The changes which are liable to take place in it are wrought before our eyes: we have the privilege of watching them. Now such a gland will sometimes enlarge, in consequence of the deposition of tubercular matter in its substance: it will grow large and hard without there being any pain, or heat, or redness, observable; and it may remain in that state for weeks, or months, or years.

But in the majority of instances the absorbent gland, after remaining for a certain time in this condition, will undergo, and cause, other changes. Pain, heat, and redness will ensue; the hard gland will soften; the integuments will grow thin, and at length give way; the softened tubercular matter, mingled with pus, will escape; and then the pain and heat and redness—the inflammation, in short—will disappear; and the abscess will heal, leaving behind it nothing more than a slight scar. This process may happen to one such gland; or to more than one *simultaneously*; or to several in *succession*.

In this case there has been no more inflammation than was just enough to accomplish its purpose of removing from the body the tubercular matter. The inflammation has not transgressed what Dr. Latham has called its specific limit.

But again, it may go beyond that limit; it may be both more severe and more extensive than is necessary for the removal of the tubercular matter in the diseased gland. It may pervade the whole neck, giving rise to diffused redness, and swelling, and pain: and the whole of the subcutaneous areolar tissue between the angle of the jaw and the clavicle may be loaded with effused serum and pus.

All this you may see almost any day in the wards or waiting-rooms of a hospital. And Dr. Latham has happily chosen this affection of the cervical glands to elucidate what happens when the tubercular matter is deposited in the *lungs*, where one cannot see the changes it is suffering or producing.

Tubercles in the lungs may remain for an indefinite period of time, in their crude state; never softening at all, or softening only at a very late period. Or they may give rise to just so much of inflammation, and no more, in the pulmonary tissue surrounding them as is sufficient to bring about their own softening and subsequent expulsion. Or, lastly, the tubercles may excite much more inflammation of the lung around them than is requisite for their elimination: inflammation of every degree, and of any extent.

Now to the first two cases, when they occur, he gives the name of *unmixed* phthisis: the third he calls, on the other hand, *mixed* phthisis. We learn from auscultation whether the case be one of mixed or unmixed consumption; *i. e.*, we hear, in the unmixed form, the sounds or the modifications of sound which result from the presence of tubercles or of vomiceæ; and we hear these morbid sounds only: in every part of the lung where they are *not* audible, we hear the vesicular murmur of health. But in the mixed form we also hear these sounds. True, and we hear other morbid sounds besides. The tubercular disease is mixed with common inflammation; and we hear the sounds that denote common inflammation of the mucous membrane, or

of the substance of the lung — sibilus, or large or small crepitation — we hear these sounds *mixing* themselves with the sounds which belong to the tubercular affection.

This distinction is of considerable importance, for it concerns the *treatment* of the malady. The tubercular disease, when established, is beyond our power. The inflammation which is incidental to it we may hope to alleviate or to remove. It is in the stage of vomicæ that the disease commonly assumes the mixed character; and sometimes the bronchial or vesicular effusion upon which the added sounds depend, may be got rid of by the seasonable application of a few leeches, or of cupping-glasses, or of a blister, or by a moderate bleeding from the arm, and the disease be brought back again, for a time at least, within its specific limits: and the patient be relieved from much distress, and imminent danger. It is upon this principle that Dr. Latham explains the fact that most consumptive patients improve considerably, soon after their admission into the wards of a hospital. The poor are necessarily much exposed to those causes which tend to complicate the tubercular disease. The tubercular disease may as yet be slight and limited; but the superadded mischief, the bronchial and vesicular effusion, may be immense; and this being submitted, often for the first time, to treatment, upon their admission into a hospital, is for a while removed.

Now if we had not the advantage of the method of auscultation, we could not ascertain these differences, nor detect them when they existed. You will perceive, I am sure, their practical importance.

Of course the more ready the surrounding lung is to take on inflammation — in other words, the stronger the disposition in the complaint to assume the mixed character — the more rapidly fatal is it likely to be.

But of the unmixed form of phthisis Dr. Latham has made two interesting varieties: and the truth of the distinctions drawn by him will be more manifest to you, the more you see of this terrible disease. In one of these varieties the lungs are apparently tenanted by a multitude of tubercles, which remain crude and unaltered for a considerable length of time. In the other, successive *crops* of tubercles appear to form: or at any rate the tubercles ripen and are expelled in successive crops: and there may be long intervals between each crop and the next.

Dr. Latham thus describes the former of these two varieties: — “An individual loses the complexion of health, and becomes thin: he coughs a little; but perhaps he has no notable fever, and no constant acceleration of pulse.” Upon auscultation of his chest it is found that there is dulness beneath one or both clavicles, or about one or both scapulæ, and an indistinct respiratory murmur in those parts; but the vesicular breathing is free and perfect in every other part of the lung. Here we have tubercles, crude, and in the upper lobe alone: and this state of things may endure for years, without variation; the patient remaining always a great valetudinarian. “To such a patient (says Dr. Latham) it is a continual puzzle why he does not get well. He consults an infinite number of medical men: and it is remarkable that he gets no comfort or satisfaction from those who understand his disease the best, and the greatest comfort and satisfaction from those who understand nothing about it. Those who know what it is, out of kindness do not tell him the truth, and they cannot asseverate a falsehood stoutly enough to carry any weight with it: whereas they who know nothing about it affirm boldly and unhesitatingly that *it is all stomach*; really believing that the whole and sole disorder is in the stomach, and that it is within the reach of an easy cure.”

But at length — perhaps after a very long period — vomicæ are formed; and then the patient sinks rapidly, and his lungs after death are found riddled by cavities and stuffed with tubercles; but every part of them not occupied by tubercles or vomicæ is crepitant and healthy. In these cases, disease lingers long in the crude stage; new tubercles are added, probably, year after year: but none of them soften. They do not excite inflammation in the lung around them. You recognise the presence of the tubercular matter by the ear; but there are no vomicæ. At last vomicæ are formed, many at the same time or in rapid succession, and the patient presently succumbs.

The other variety of unmixed phthisis may be just as protracted as this; but its character and progress differ materially. In the former case the patient's condition was one of invariable ill health; in the one I am about to mention he has fits of ill

health, and fits of comparative good health. He spits for a time considerable quantities of puriform matter, and then ceases from expectorating altogether. He has hectic fever, and then throws it off, and then suffers it again: wastes, and recovers his flesh, and again loses it. You will find such cases common enough; and in these cases the morbid sounds will be correspondent to the symptoms. During the fits of illness you will hear gurgling respiration or gurgling cough at the apex of one or both lungs; and during the fits of good health you will hear cavernous respiration or pectoriloquy in the same parts; but everywhere else you will hear a clear sound of vesicular breathing. Here the tubercular matter excites just enough inflammation around it to achieve its own expulsion, and no more. The lung is destroyed bit by bit. Fresh portions of tubercular matter are deposited; these ripen and soften, and are expectorated, and a vomica is the result; and then there is a period of quiet. And there being still a large portion of each lung to breathe with, the patient regains more health and strength in the intervals of his attacks, than the former patient possessed habitually.

But in this form of unmixed pulmonary consumption, a period at length arrives when the patient does not revert to the former state of apparent health. The quantity of lung that has now been destroyed forbids it. You hear the sounds proper to tubercular disease over a large space, between the clavicle and the mamma, or anywhere about the scapula, on one or both sides; yet still that part of the lung which is free from tubercles and vomicae is pervious and healthy: but the hectic continues, the emaciation increases, and the strength declines; and the fatal consummation arrives.

Of these two varieties of genuine and unmixed consumption, the first is the most hopeless. The tubercles are numerous; they probably go on increasing in number though they do not soften; there is not, and there cannot be, any, even temporary return to health, either real or apparent.

Whereas, where the tubercles come singly, or in successive crops, and rapidly soften, and are expectorated; and where some long time interposes between the crops; the health and strength return, and there is just a chance that no more tubercles may form. It is in this variety of unmixed phthisis that a natural cure, by the contraction and cicatrization of a vomica, may by possibility take place. We cannot expect, we scarcely dare permit ourselves to encourage hope, that the disease *will* cease in that manner: but if it cease in any form of the malady, it is in this.

[In regard to the curability of pulmonary consumption, Dr. Wood, in his *Treatise on the Practice of Medicine*, remarks, as follows:—

“I am not one of those who believe that phthisis is in all cases necessarily fatal. On the contrary, I believe that, in one stage or another, it is occasionally cured, or at least ends in perfect recovery. It is no very unfrequent event to see threatening symptoms of phthisis give way under suitable treatment. It cannot be proved, with absolute certainty, that these symptoms were tuberculous; because the evidence of dissection is wanting, and the physical signs are not sufficiently positive, in mild cases of early phthisis, to authorize a certain conclusion. But they are undistinguishable from symptoms, which, in other cases, are the forerunners of confirmed phthisis; and we have abundant evidence from dissection, that tubercles are capable of undergoing favourable modifications. The probability is, that the tuberculous matter is absorbed, and sometimes, as shown by dissection, replaced by calcareous matter; and, if the diathesis be so far subdued as to prevent the deposition of other tubercles, before these have completely run their course, the disease may be said to be cured. The circumstance that such remains of tubercles are not unfrequently found in the lungs of old persons, who have died of other diseases, would seem to show, that these cures are sometimes permanent.

“But this is not all. It occasionally happens, that consumptive symptoms disappear entirely even in the second stage of the disease, after the formation of a cavity. This event, it is true, is comparatively rare; but some such cases have probably fallen within the notice of almost every practitioner of extensive experience. Even should the disease ultimately return, still, the case may be said to have been cured; as the occurrence of a second attack of pneumonia is certainly no proof that the first was not cured. But there have been cases in which no return of the symptoms has taken place during the residue of life, even though considerably protracted. Two instances of this kind have occurred in medical men of this city. One of the patients was

affected, when a young man, with all the symptoms of phthisis, including frequent attacks of hæmoptysis, severe cough, hectic fever, &c., from which he completely recovered, and continued exempt up to the time of his death, which occurred many years afterwards of typhoid fever. (See *N. Am. Med. and Surg. Journ.*, viii. 277). The other was my preceptor and friend, the late Dr. Joseph Parrish, who in early life laboured for a time under the symptoms of phthisis, and after his death, at an advanced age, was found to have several cicatrices of the upper part of one lung, which were obviously the remains of tuberculous cavities. (See *Am. Jour. of Med. Sci.*, xxvi. 256). The probabilities upon the whole are, that each tubercle has a tendency towards health, and, if alone, would in time end in perfect recovery; so that the great fatality in phthisis consists in the continued predisposition which causes the constant or frequently repeated deposition of other tubercles, before those first deposited have had time to run a favourable course. We may, therefore, always entertain some hope, if applied to in the early stage, in cases of no great severity, of seeing a cure effected; and, even in the second stage, when the diathesis is not very strong, or the local disease extensive, there is no reason for absolute despair. Even in cases which appear to offer no chance of ultimate recovery, we may hope to be able very much to prolong the duration of the complaint, and sometimes even to add years to a valuable life. There is an individual now pursuing an active business in Philadelphia, though with a cavity in his lung, who eight years since was under my care with severe cough, copious purulent expectoration, night-sweats, hectic paroxysms, and great emaciation and debility. When the second stage is clearly established, with severe constitutional symptoms, and the physical signs of extensive disease in the lungs, there is scarcely any ground for hope. If to the ordinary symptoms, in such instances, are superadded continued vomiting and diarrhœa, the case may be considered as quite desperate; and speedy death may be expected." — C.]

This grouping of the different characters under which pulmonary consumption may appear, has been performed by Dr. Latham with perfect fidelity. There is nothing overstrained or fanciful about his sketch; it is after nature; and it is by the hand of a master. And there is something very refreshing in original views of this kind. Vastly more instructive too they are, than those presented by a dull compilation. I therefore again recommend you to study his little volume. I am sure that I have derived much useful and usable knowledge from it: and so also may you.

There is another form still of tubercular consumption which Dr. Latham has not omitted to notice; but his observations on this form are not so new. It is a striking, but not very common form; and it is sure to arrest the attention of the practitioner when it does occur. I have met with three or four examples of it. The phenomena are of this kind. The patient has difficulty of breathing, cough, hæmoptysis perhaps, night-sweats, and much hectic fever; the symptoms in short which constitute the acute phthisis of some authors. But if you listen to the chest, you do not hear the sounds that are peculiar to phthisis: you do not find dulness confined to the upper lobes, or pectoriloquy, or gurgling respiration: but you rather find the superadded sounds which accompany mixed phthisis; small crepitation all over the lungs, succeeded by an absence or deficiency of the proper breathing everywhere. Meanwhile there will be none of the expectoration which is characteristic of phthisis. In short, you would not suppose that the disease was phthisis at all. Yet it must be called such, for after death you find the lungs thickly bestrewn everywhere with what I spoke of before as the granulations of Bayle; nascent tubercles, myriads of them, grey and minute: what many persons call miliary tubercles. The tubercular matter, from some cause whereof we know nothing, is thickly and uniformly sown over the whole of the air-passages, or throughout the entire extent of the lungs, and its sudden presence there in such abundance excites inflammation, which masks and conceals the specific disease; and the true nature of the case is not suspected till after the patient's death. All the instances that I have seen — three or four only in number — were supposed by me to be cases of extensive inflammation of the lungs; and so indeed they were, but they were something more. The tubercles, doubtless, were the cause of the inflammation; and not the inflammation the cause of the tubercles.

From what I have been stating you will perceive how difficult it is to say what is the ordinary *duration* of phthisis; concerning which a question was put to me at the

close of the last lecture. The disease may be present for some time without declaring itself by any marked or unequivocal symptoms; and therefore without attracting attention. But taking the cases as they occur, and estimating the duration of the malady from the time when it first manifests itself in a decided form, we find there is quite enough of variation to warrant the distinction that has been made by authors between chronic and acute phthisis; or, to use the more popular and more expressive phraseology, between slow and galloping consumption. The following tabular statement of the results observed by Bayle and Louis, will give you a somewhat more precise notion of the general progress and duration of the disease. The whole number of cases noted was 314. Of these, 24 died within three months; 69 between three and six months; 69 also between six and nine months; 32 between nine and twelve months; 43 between twelve and eighteen months; 30 within from eighteen months to two years; 12 between two and three years; 11 between three and four years; 5 between four and five years; 1 between five and six years; 3 between six and seven years; 1 between seven and eight years; 3 between eight and ten years; and 11 between ten and forty years.

You will remark that, so far as this account goes, more than one-half of the whole number died within nine months from the time when the disease first became manifest. This agrees with the experience of the late Dr. Gregory, of Edinburgh. He used to state that the ordinary duration of phthisis was about six months; that sometimes it lasted only two or three months; and that he had seen one case which proved fatal on the seventeenth day after the symptoms were first observed. On the other hand, he had known one man who was at least 72 years old when he died, in whom symptoms of phthisis first appeared at the age of 18, and who was never free from them during all the intervening period; being often hectic, and frequently spitting blood. It has been my melancholy task to watch the long decline, and the death at last, of a statesman who served his country well and strenuously, yet of whose years and health a precisely similar description to this would be true. The *average* or *mean* duration of consumption has been computed to be about two years. This is a different thing, you will please to observe, from its *ordinary* duration.

There are many other points in the statistical history of phthisis well worthy of attention and inquiry; but I have not time to go into them in any other than a summary manner. This part of the subject is very well worked up in Sir James Clark's lucid and sensible book upon Consumption: but you will have perceived, from the references I have so frequently had occasion to make to M. Louis, that *his* work is the great storehouse or treasury of tabular information, with respect to the facts of tubercular phthisis.

It is an interesting question to determine at what period of human life consumption numbers the most victims. There are two short tables, one drawn up by Louis, containing observations relative to 123 cases, and the other by Bayle, respecting 100 — which throw some light on the question. The two tables agree, in the main, very closely. Thus, from the age of 15 to that of 20, Louis met with 11 deaths from phthisis, Bayle with 10; from 20 to 30, Louis met with 39, and Bayle 23; from 30 to 40, Louis 33, Bayle 23; from 40 to 50, Louis 23, Bayle 21; from 50 to 60, Louis 12, Bayle 15; from 60 to 70, Louis 5, Bayle 8. You see from this account how erroneous the common notion is, that consumption does not occur at an advanced period of life: that a person who has reached his thirtieth or fortieth year is thenceforth safe from that disease. From these two tables, and others collected by Sir James Clark, it appears that, taking decennial periods, the greatest number of deaths from phthisis happens between the ages of 20 and 30: the next greatest number from 30 to 40: the next from 40 to 50: and that, after these, it is a doubtful matter whether more perish of consumption between 50 and 60, or between 15 and 20, which last is only one-half of a decennial period. These calculations refer, as you will remark, to human life after the age of puberty. Before that age, tubercular disease is fearfully common, especially in infancy and childhood. Among 920 children (532 girls, and 388 boys) who died from the age of 2 to that of 15 years, no less than 538 (nearly three-fifths of the whole) were affected, Dr. Papavoine tells us, with tubercles.

In a report made by the physicians to the Hospital for Consumption at Brompton, the decennial periods are calculated from a different point. Their tables, which com-

prehend the cases of 2679 males and 1679 females, lead to the conclusion that, in both sexes, the "*liability to consumption* is greatest" between 25 and 35 years of age.

From the same tables, as well as from those of the Registrar-General, it appears that in *this metropolis* more men than women die of consumption. In the provinces, according to the Registrar-General's returns, there are more deaths from phthisis among women than among men.

Statistical researches are of still greater interest, perhaps, when they elucidate the influence of different trades and occupations in calling phthisis into existence. Sir James Clark has brought together much curious information on this point. There are certain occupations which appear to provoke pulmonary consumption by the direct application of local irritants to the lungs themselves: and there are others which tend indirectly to bring on phthisis, by lowering the tone of the general health: by producing debility and cachexia. But these two causes often go together: and it is difficult to estimate with accuracy their separate effect. The workmen whose employments have a directly irritating operation upon the respiratory organs, are stone-masons, miners, coal-heavers, flax dressers, brass and steel-polishers, metal-grinders, needle-pointers; and many others who of necessity inhale during their labour an atmosphere loaded with irritating particles of matter. But, then, most of these men work also in towns, and remain for many hours day after day in a constrained position, in crowded or in close apartments. Moreover, some of these occupations, being sedentary, and requiring no great muscular power, are unfortunately selected, for that reason, by persons who are naturally of feeble or delicate constitution. On the other hand, butchers, fishermen, and their families, and farm-servants, are said to be comparatively free from phthisis. Beddoes ascribed this exemption to the use of animal food by these classes: but much of their better health is due, no doubt, to their habits of active exercise in the open air; and to the circumstance that such employments demand a certain amount of bodily strength and energy, and therefore are not likely to be adopted by weak and scrofulous individuals. It is obvious that the whole inquiry is beset with sources of fallacy. We know, however, on the evidence of undoubted facts, that certain occupations do tend to induce pectoral complaints, and to shorten life. Dr. Knight, of Sheffield, informs us that fork-grinders, who are what are called dry grinders, die there of the *grinder's asthma* or *grinder's rot*, before they are thirty-two years old. Razor-grinders, who grind wet and dry, live a little longer: the moisture diminishes, of course, the number of floating particles of metal. Table-knife grinders work on wet stones, and survive till they are between forty and fifty. I must refer you to Sir James Clark's book for similar facts with respect to the inhalation of silex, of the dust of mines, and so forth. Without pretending to assign to each alleged injurious influence its precise contribution of mischievous effect, we must be content, at present, with the practical inference, that such employments should, if possible, be avoided by all those who show any tendency to scrofulous disease.

Is phthisis *contagious*? No: I verily believe it is not. A diathesis is not communicable from person to person. Neither can the disease be easily (if at all) generated in a sound constitution. Nor is it ever imparted, in my opinion, even by one scrofulous individual to another. Yet in Italy a consumptive patient could not be more dreaded and shunned if he had the plague. And in this country the suspicion will now and then arise that the disease may be infectious. A girl dying of phthisis is nursed by her sister, who afterwards droops and dies of the same complaint. Here the presence of the peculiar diathesis is strongly presumable. But the parties may be different in blood. A wife watches the death-bed of her consumptive husband; and presently sinks herself under consumption: and there may be no traceable or acknowledged example of scrofula in her pedigree. Yet even here the latent diathesis may fairly be presumed to have existed. Very few families are perfectly pure from the strumous intermixture. The predisposition may be slight; it may be dormant for a generation; or, like other inherited peculiarities, it may alight capriciously on some individuals only of the kindred. In both the supposed cases there have been other influences at work, more authentic than the alleged contagious property, in calling forth the fatal malady. Watching, the want of rest, confinement in the unwholesome air of a sick chamber; and, above all, protracted mental anxiety, than which no single cause perhaps has more power to foster and forward the inbred

tendency to phthisis. The disorder, I am satisfied, does not spread by contagion. Nevertheless, if consulted on the subject, I should, for obvious reasons, dissuade the occupation of the same bed, or even of the same sleeping apartment, by two persons, one of whom was known to labour under pulmonary consumption.

The *treatment* to be adopted, and the plan of regimen to be observed, in respect of tubercular phthisis, resolve themselves into the methods of *prevention* when the disease is *likely to occur*; of *arresting its progress* when that disease is *incipient or limited in extent*; and of *alleviating the most distressing symptoms*, when no hope remains of stopping its course, or of averting its fatal close.

With regard to the *prevention* of the disease, in those, who, by inheritance, or by circumstances, are predisposed to it, a great deal might be said; but the subject belongs rather to the head of medical police, or hygiene, than to the practice of physic. We deem that a person *has* that predisposition, which is almost a necessary condition of the development of tubercular disease, when we observe those marks of the serofulous diathesis which I pointed out in an earlier part of the course: or when we know that the parents possess that peculiarity of constitution: or when brothers or sisters have displayed it. It would be well indeed for society if the multiplication, and diffusion, of the strumous diathesis could be checked, by a prudent avoidance of ill-assorted marriages. But we cannot say—no legislature could say—to a serofulous man or woman, you shall not marry, and propagate serofula. It is reasonable, however, to conclude, and the conclusion is amply borne out by the observation of facts, that where both parents are strumous, the child will, in all probability, be doubly so; or that, at any rate, its chance of escaping the serofulous disposition will be small. It is very desirable, therefore, that correct notions on these subjects should be generally prevalent: and that persons who are conscious that serofula in any of its shapes exists in their family, and *à fortiori* they who know that it exists in their own corporal frame, should avoid allying themselves with persons who are in the same predicament: and this prudence might be enforced if they could be made to foresee the suffering and misery its neglect is calculated to inflict upon their offspring. Intermarriages of persons of the same family, when that family is subject to tubercular disease, are earnestly to be deprecated. But on these points our advice is seldom asked.

We are liable, however, to be consulted respecting the mode of *warding off* serofulous disease in those who have derived a hereditary tendency to it from their ancestors. Now the first and most effectual prophylactic in such cases, is residence in a mild, and dry, and equable climate: and next to that is the avoidance of all causes likely to foster the morbid tendency. I need not repeat what I formerly told you on this subject. Pure air; nourishing, but unstimulating food; moderate exercise; early hours; cleanliness; warm clothing; and abstinence from excessive study, from severe bodily toil, from occupations in their nature unwholesome, from such callings also and employments as are fertile of care and anxiety, and from vicious and exhausting indulgences of all kinds: these are the topics upon which we must insist, when our advice is sought for respecting the means of preventing consumption in children or others, who are in danger of contracting it.

But when the disease *is present*—when tubercles actually exist, and are ascertained to exist in the lungs—may the progress of the disorder be ever suspended by a change of climate? Indeed I believe it may: but only in certain cases, and in certain stages of the disease. When phthisis occurs in either of its slow and unmixed forms, the question of a change of sky will be worth entertaining. In that form in which tubercles remain long in the crude state, I believe life may be preserved or lengthened by leaving this country, and residing under a higher and more equable temperature, provided that no softening of the tubercular matter has yet taken place. And in the other form—when a vomica or vomicae have occurred, and the strength is apparently restored, and the remainder of the lungs gives out the sounds of health—in that case also I would recommend a voyage to a milder and less changeable climate to those persons who could afford to migrate, and to whom it was a matter of importance that they should prolong their earthly existence. I believe there is no place to which such persons could go with more hope of benefit than to Madeira. Pau in the Pyrennees, Malaga on the east of Spain, Egypt, have each their advantages for phthysical patients. Madeira may be regarded as the type of the moister

and more *soothing*—Egypt of the drier and more *bracing* climates. There are, however, places on our own coast that offer no ineffectual substitute for warmer lands beyond the sea, to those who cannot so conveniently expatriate themselves. Hastings, for instance; the Isle of Wight; Clifton; and more especially Torquay, on the coast of Devonshire; and Penzance, or its neighbourhood, in Cornwall. In those southern and sheltered spots the patient may sometimes pass the colder weather of our winter and spring months in comparative security. If, however, the lungs are already in a state of rapid disorganization, no benefit, but on the contrary much inconvenience and useless expense, will result from change of place, unless that place in which the patient is residing be notoriously unhealthy. When I am asked about removal, either to another country, or to some distant part of our own, and the state of the patient is such as I have just alluded to, I always advise that he should *not* forego the comforts of his home—and leave his family and friends—to seek advantages which he will not find, among strangers, and amid the discomforts of a lodging perhaps, or an incommodious dwelling. I think it wrong, and cruel, to send people away merely to die: and that many are so sent to this place and to that, in the almost certain prospect of their never returning, no one, I think, can doubt.

[It is well remarked by Dr. C. G. Comegys, in a very sensible paper on the Etiology and Curability of Phthisis Pulmonalis, communicated to the Ohio State Medical Society, at its session of 1854, that phthisis pulmonalis is a common disease of all civilized nations; and the remark may be extended, almost as fully, to embrace the people, whether savage or civilized, in all parts of the habitable globe. It does not, however, prevail to the same extent in all countries, and the most secure residences for the predisposed would seem to be those so far north as to escape the greatest vicissitudes of the seasons. Thus in Stockholm, the deaths from pulmonary consumption only amount to one-fifteenth of the entire mortality, while in London, Paris, and Berlin, they amount to almost one-fifth. In some of the German cities, the proportion is also much larger than in St. Petersburg.]

Many writers still hold out the idea that warm climates are comparatively exempt from pulmonary phthisis; but since accurate statistical research has been directed to the investigation of the question, the deaths from the disease have been found to be as common as in higher latitudes. Thus, for the eastern continent, the rate is almost as great at Rome, Naples, Madrid, Lisbon, Marseilles, Malta, the Ionian Isles, and the north of Africa, as it is in England.

From the researches made on our own continent, the same result is established. In fact, according to the statistics collected by the late Dr. Drake, from the reports of the British Army, and the sanitary publications of some of the cities on our seaboard, the proportion of deaths from phthisis is greater in the south than in the north; and we may add that the same general fact is also established by the medical reports of the Army of the United States.

These statistics relate to the West Indies, as well as to the British possessions further north. Statistics collected in Brazil and Martinique, by Drs. Russ, Jobins, and Sigaud, show that consumption of the lungs is as destructive to life in those places as in the United States. In the Island of Cuba, the deaths from phthisis for the City of Havana constitute considerably more than one-fourth of the entire mortality, and for the rural districts upwards of twelve per cent. In the City of New Orleans, La., the deaths from phthisis constitute 9.51 per cent. of the entire mortality. In neither the Island of Cuba nor in New Orleans, are the deaths from the disease chiefly confined to strangers who visit these places with a view to the recovery of their health, but occur in a very large proportion among the native population.

According to Dr. A. K. Johnson (*Geographical Distribution of Health and Disease*), consumption is rare in the Arctic regions, in Siberia, Iceland, the Faroe Islands, the Orkneys, Shetlands, and Hebrides. And, in confirmation of the opinion that it decreases with decrease of temperature, Fuchs shows, from extensive data, that in Northern Europe it is most prevalent at the level of the sea, and it decreases with elevation to a certain point. At Marseilles, Oldenburg, and Hamburg, near the seaboard, the mortality from this cause is about 25 per cent.; at Esehwege, 496 feet above the sea, it is only 12 per cent.; and at Brotterode, 1800 feet above the sea, only 0.9 per cent.

The subject of the effects of climate on tuberculous disease is very ably examined by Dr. Edwin Lee, of London, in a dissertation which obtained the Fiske Fund prize from the Rhode Island Medical Society. (See *Amer. Journ. Med. Sciences for Ap.*, 1857.) As the general conclusions of the author have a more or less direct bearing upon the subject before us, we present them here entire.

1. Tuberculous disease of the lungs is curable in an indefinite proportion of cases, which proportion would doubtless be greatly increased by the more general employment of climate, and the other hygienic and remedial means, to which recourse has been had up to the present time, only in exceptional cases, frequently when the disease has arrived at too advanced a stage to derive permanent amelioration from the use of any means. Even when a cure is not practicable, the progress of the organic lesion may often be arrested or retarded by the suitable employment of these agents.

2. The formation of tubercle depends, most probably, upon an impoverishment of the blood, characterized more especially by a diminution of the normal amount of its globules, together with an alteration in its composition; occasioned chiefly by deficient activity of the skin—considered as an excrementitious organ—whence substances are retained in the blood which ought to be eliminated from it, some of which, chemical analysis has detected the existence of in tuberculous matter—and also as a supplementary organ to the lungs in the function of respiration.

3. Statistical documents, as well as the investigations of impartial observers, have shown that pulmonary consumption occurs, much more frequently than elsewhere, in countries and localities where a humid state of the atmosphere predominates, and also that it prevails chiefly among those classes of the population who are most exposed to this and other influences which tend to depress the vital powers—particularly the activity of the capillary circulation—and, consequently, to vitiate the blood by suppressing the cutaneous transpiration (sedentary mode of life, prolonged anxiety, grief, and other depressing emotions, &c.).

4. On the other hand, tuberculous diseases are of comparatively rare occurrence in cold and dry climates, where the energy of the circulation and of the cutaneous functions, is maintained by the substantial food, and by the active mode of life of the inhabitants, which suffices to preserve them, in great measure (as respects pulmonary consumption), from the pernicious effects of the inclemency and variations of the weather to which they are continually exposed. Consumption is likewise rare in warm and dry countries, where the inhabitants live a good deal in the open air, and where the insensible perspiration is kept up, without muscular effort, by the influence of the climate. On the other hand, it is frequent among the natives of several countries where the climate is hot and moist (the West Indies, &c.), on account of the relaxation of the system, and of the repression of the insensible perspiration, produced by the combined agency of heat and moisture.

5. In some localities favoured in point of climate, though tubercular phthisis is seldom met with among the inhabitants in general, it may nevertheless be tolerably frequent among those of the lower orders who are exposed to the influence of the anti-hygienic causes which mostly tend to induce tubercular cachexy in all countries. Many individuals, in such localities, as well as soldiers serving at stations where the mortality from consumption is small among the general population, nevertheless die from diseases of the organ of respiration simulating phthisis, which are often erroneously considered as such.

6. The chief indications in the treatment of pulmonary tubercularization by means of climate, are, first, to remedy as far as possible the morbid condition of the blood, which constitutes the cachectic state, and, by this means, to prevent or arrest the formation of the morbid product; and secondly, to allay the general and local excitation occasioned by the organic lesion. These indications are not unfrequently opposed the one to the other, and in many cases the practitioner is obliged to restrict himself to endeavouring to fulfil the second, and to palliate the symptoms by pharmaceutical remedies.

7. Change of air, and a residence, more or less prolonged, in warm countries during the winter—the selection being determined by the particular circumstances of individual cases—ought to be considered as the means best calculated to fulfil the first indication, and should be recommended in all chronic cases as early as possible.

8. The beneficial influence of climate in arresting the progress of pulmonary tuber-

culization, would be so much the more marked in proportion as the disease is recent, and as the patient could be the more speedily removed from the influence of the causes which may have contributed to produce it.

9. The localities which would generally be best suited for the winter residence of patients labouring under pulmonary phthisis, in the early stage, are those which, together with a suitable climate, possess resources for mental occupation and diversion, which would induce them to pass a great portion of their time in the open air, avoiding, however, occasions of fatigue.

10. A prolonged residence in any place where the temperature is very equable and the atmosphere calm, is not advantageous to patients when it is a question to procure the restoration of the blood to its normal state. On the contrary, a moderate agitation of the atmosphere is favourable to them by exciting the insensible perspiration, and by making them, so to speak, breathe by the skin as well as by the lungs.

11. The choice of a climate should be determined by the patient's temperament, the condition of the system, and the more or less advanced state of the disease. In general, warm and dry localities best suit persons of a lymphatic or scrofulous constitution, where the circulation is languid; these are, on the other hand, often too exciting for individuals of a sanguinary or nervous temperament, in whom there is irritability of the air-passages, a disposition to inflammation or to hæmoptysis, with acceleration of the circulation. Such patients would more frequently find themselves better where the atmosphere is somewhat moist, not liable to great transitions, and of which the action is consequently sedation. A similar climate is likewise better adapted to patients in the more advanced stages of the disease, when it is deemed advisable to recommend to these a change of climate.

12. Most persons with pulmonary consumption, who are natives of northern countries, would be benefited by a residence, during a part or the whole of winter, in a warm climate, even though it were humid—provided the disease were not too much advanced—and from the mere passage from a cold to a milder temperature. Many patients, in whom there exists a state of general or local excitation which requires the employment of sedative remedies, would derive permanent advantage from the action of a warm and moist atmosphere, which would tend to allay irritation and diminish the amount of bronchial exhalations. But the too prolonged influence of such an atmosphere, by relaxing the system, would render most patients liable to an aggravation of the disease, if, on changing the place of their abode, they exposed themselves to the action of a climate having a different character, or to any of the accidental causes of the disease.

13. In many cases of incipient tuberculization, in order to derive a curative action from the influence of climate, we should, so to speak, regulate the doses either of stimulation or of sedation. As the sedative action of an equable temperature and a moist atmosphere, would, in many cases, be advantageous up to a certain point, and afterwards prejudicial; so, in like manner, that of a dry and exciting climate, which may at first have been favourable, when too much prolonged, not unfrequently causes an aggravation of the symptoms, and sometimes a state of general irritability, which, notwithstanding the use of remedies, persists or increases, unless the patient be transferred to a climate more suited to his actual state; which, however, is frequently not practicable.

14. Among the climates most in repute for their efficacy in retarding the progress of pulmonary consumption, there exists a considerable variety with respect to equability of temperature, the state of dryness or moisture of the atmosphere, the degree of warmth, &c. The climates of Upper Egypt, the southeastern coast of Spain, are the most remarkable for their warmth and equability in winter, as well as for the dryness of their atmosphere. To these climates, Hyères, Nice, Menton, Malta, and Naples, approximate nearest as respects dryness, though differing materially in other respects. The West India Islands and Cuba may be mentioned as a type of hot and moist climates. Among the intermediate climates characterized by variable degrees of warmth, equability, and humidity, are Madeira, Algiers, Pau, Pisa, Rome. The three latter have a sedative action, often depressing the vital powers of persons in health, as well as of many invalids.

15. The atmosphere of marshy localities, where endemic intermittent fevers prevail,

is neither preservative nor curative of pulmonary consumption, as has been supposed by some physicians; the disease being tolerably frequent in many of these localities.

16. A residence in the places whose climates are best suited to the particular cases, exerts not only a directly advantageous influence in arresting or retarding the progress of the disease, but likewise, inasmuch as patients are thereby placed under the most favourable hygienic conditions, for promoting the efficiency of remedies which would otherwise be inefficacious.

17. Sea-voyages are often beneficial in the early stage of pulmonary tubercularization, when patients do not labour under urgent symptoms; when the strength is not much diminished; when they have a taste for voyages, and are not likely to be prejudicially affected by the monotonous mode of life usually led at sea, and provided there be no grounds for apprehending the exhaustion frequently produced by sea-sickness in long voyages.

18. The advantage which patients sometimes derive from sea-voyages mainly depends upon the continued renovation of a pure air, which acts as a tonic, promotes the insensible perspiration, and the activity of the other functions of organic life. The saline impregnation of the sea air may possibly somewhat conduce to its strengthening effects, though it has not been demonstrated that a residence near salt-works, and the inhalation of an air strongly impregnated with saline vapour, has been followed by special beneficial effects in cases of consumption.

19. Land-travelling through an agreeable country is better suited to consumptive patients in general than are sea-voyages, because, in addition to the effects produced by renovation of the air, it acts in a favourable manner on the *morale* of those invalids in whom it does not occasion too much fatigue. It can, also, be undertaken in the society of parents or friends. Those who travel by land can stop where they please, and they have within reach the medical assistance which their cases may require. It is only, however, when land-travelling is undertaken in suitable weather, and by easy stages, that it can be expected to be attended with benefit, and with comparatively little risk.

20. The climate of several places possessing mineral springs is very favourable to many patients affected with tubercular disease, in the summer season. The operation of appropriate mineral waters—when these agents are not contraindicated—powerfully tends to improve the quality of the blood when vitiated, and to increase the activity of the various secretions, especially those of the skin. It imparts a salutary impulsion to the movements of the economy, and prepares patients for deriving the greatest possible advantage from the influence of a suitable winter climate.

Dr. Coolidge, in his Statistical Report on the Sickness and Mortality in the Army of the United States, remarks that “the climate of those broad and elevated tablelands which skirt the base of the Rocky Mountains on the east, is especially beneficial to persons suffering from pulmonary disease, or with a scrofulous diathesis. This has been known to the French inhabitants of the Upper Mississippi and Missouri for many years. The reports from the line of posts stretching from the Upper Platte through New Mexico to the Rio Grande, give a smaller proportion of cases of pulmonary disease than those from any other portion of the United States. The air in this region is almost devoid of moisture, there are no sudden changes of temperature; the depressing heats of the eastern summers are never felt; and although in the north the winters are extremely cold, a stimulant and tonic effect is the only result of exposure in the open air. It is of great importance that the climate of this region should be generally known, that the present injudicious course of sending consumptives to the hot, low, and moist coast and islands of the Gulf of Mexico should be abandoned. The towns of New Mexico should be selected as a refuge for those showing a tendency to disease of the lungs, or scrofula; anywhere east of the Rocky Mountains, and west of the region where ‘northers’ prevail.”

In a recapitulation of the deductions in relation to the influence of climate on patients predisposed to or affected with phthisis, it is shown by an examination of the consolidated table given, that, with the exception of West Point, the lowest ratio of cases of consumption occurs in New Mexico, being only 1.3 per 1000; and the highest in the South Atlantic region, where it is 9.2 per thousand. This agrees with the previous statements of Dr. Forry, based upon similar data, with those drawn from statistics of the British army, and with those of Alexander Keith Johnson (*on the*

Geographical Distribution of Health and Disease), inferred from a still wider examination of medical geography.

The general conclusions of Dr. Coolidge are as follows :—

“*First.* That temperature, considered by itself, does not exert that marked controlling influence upon the development and progress of phthisis which has been attributed to it.

“*Second.* That the most important atmospherical condition for a consumptive is *dryness*.

“*Third.* That next to *dryness* in importance is an *equable* temperature—a temperature uniform for long periods, and not disturbed by sudden or frequent changes. A uniformly *low* temperature is much to be preferred to a uniformly *high* temperature. The worst possible climate for a consumptive is one with long-continued high temperature and a high dew-point. — C.]

You will find a great discrepancy of opinion among authors, and among practitioners with whom you may converse, with respect to the *regimen* which consumptive persons should follow. One man gives all his phthisical patients beef-steaks and porter; another restricts all his to vegetables and asses' milk: and each will boast, and bring forward most triumphant examples, of the *success* of his system. Now it is quite obvious that for a sick person who receives benefit from the one of these plans of diet, the contrary plan could scarcely be otherwise than injurious; and reason at once suggests that there must be some distinction between the cases that get better under the one system, and those that improve under the other. Doubtless, we must have regard to the constitution and habits of the patient; and sometimes trial alone will show which plan is the most appropriate; but I believe the best clue to lead us out of the difficulty will be found in Dr. Latham's division of phthisis into mixed and unmixed. The object is, to sustain the patient's strength without exciting inflammation in his lungs. If, with the specific disease, there be conjoined an inflammatory condition of the pulmonary substance around the tubercles, or of the bronchial membrane; in such cases an antiphlogistic diet is, for the time at least, the proper diet. On the other hand, when the disease manifests no tendency to transgress its specific limits, then the diet should be generous and full: and it may be so without being over-stimulant. Debility, however induced, adds to the disposition to the deposit of tubercular matter; and therefore the debility arising from insufficient nutrition is to be avoided as carefully as is compatible with the other indication, which is, to obviate inflammation of the lung. With these hints you will be able, I trust, to strike the balance between the risk of augmenting the local mischief directly, on the one hand, and that of depressing the general strength, and so increasing the local mischief indirectly, on the other. Milk is a sort of animal diet, and it is both nutritious and unstimulating: therefore milk may, in many cases, form the staple of the food, if the patient like it, and if it agree with him: but there is much variety in this respect in different persons. I repeat, that you will too often find prejudices entertained, on the one side or the other, in regard to the diet proper for consumptive persons: but the commonest error of the two is, I believe, that of reducing the patient's strength by a needless restriction of his nutriment, lest inflammation should ensue.

Louis, should you refer to him, would be likely to lead you into the opposite mistake: for he affirms, that neither bronchitis, nor pneumonia, nor pleurisy, have any effect in exciting tubercular phthisis. But this opinion is entirely opposed to the general sense of most men of experience. Many a case of consumption can be traced back to a severe catarrh, and no further. Many, which ran a short course, were dated, within my own knowledge, from the last visitation of influenza. If M. Louis had meant that thoracic inflammation will not produce tubercles in the lungs of a person who has not the scrofulous diathesis, and that tubercles may and do arise without any previous inflammation, I should quite agree with him. But he draws his conclusions from cases of phthisis. I have no doubt whatever that the dormant predisposition is often awakened into actual disease, and that latent tubercles are often accelerated in their progress, by inflammation of the pulmonary tissues. Whether this happens directly from the local inflammation, or indirectly from its effects in lowering the vital powers, is a question which no one can solve, and of which the solution is

not of much consequence. What we are sure of is, that every one who bears a real or suspected taint of scrofula in his frame, should scrupulously guard against every known and avoidable cause of catarrh, pneumonia, or pleurisy. I hold M. Louis' doctrine on this head to be unsound and unsafe: and I mention it only to admonish you against it.

In offering you a few final observations on the *remedies* of phthisis, I shall take leave to abstain from weighing the pretensions of a number of *specifics*, which have from time to time been highly recommended; but which never have come into general use, as they would have done, no doubt, if they had been entitled to such a denomination.

In the first place we must satisfy ourselves as to the kind of case we have to deal with; whether it be mixed or unmixed. We must watch our patient: and keep him on reduced diet, and take blood in small quantities by leeches or cupping from the chest, whenever marked inflammatory symptoms arise; whether they are discovered by observation of the general or of the physical signs. The bleedings must of course be small—and palliative only of the symptoms.

Emetics, frequently repeated, have been recommended in the early stage of phthisis: partly on account of their reputed efficacy; partly on theoretical grounds; it being supposed that the tubercular matter may be thus removed from the mucous surfaces as fast as it is deposited. Of the value of this emetic plan, I am unable to speak from any experience of my own.

Counter-irritation is often of undoubted service: mustard-poultices to the chest when it is painful; or a blister, or a succession of blisters, or friction with a liniment containing croton oil, to encounter local symptoms. The effect of counter-irritation upon the progress of the tubercular disorder is apparent sometimes by accident. Dr. Abercrombie has related an example in which cerebral disease operated in this way; the previous symptoms of phthisis disappearing. In some cases mania seems to have a similar consequence, obscuring the manifestation, and probably retarding the course, of consumption. It has been often remarked—you will find this stated by Sir B. Brodie—that after amputation of a scrofulous leg, phthisical symptoms, very little noticed before, have rapidly increased. And there is another fact, in relation to phthisis, analogous to these, which it is fit you should know and attend to, viz., that the progress of consumption is often suspended by pregnancy:—and while a mother is suckling her child, if the suckling be not too long continued, so as to exhaust the mother. I suppose there is no doubt that women disposed to phthisis have been kept alive by successive pregnancies and sucklings. It is a very rare thing for a pregnant woman to die of phthisis. I have known only one instance of it. One of my patients in the hospital, a French woman, died of that disease; and we found suppurating tubercles in her lungs; and a fetus of about five months in her womb.

Riding on horseback has been strongly advised in the earlier periods of the disease. Its main advantage seems to arise from its allowing the enjoyment of fresh air, and of exercise, without putting the patient out of breath: and these advantages are great. It is affirmed that many phthisical patients remain free from cough, and those affected with hæmoptysis cease to spit blood, so long as they continue to take exercise on horseback. Gestation in a carriage, or in a boat, has the same good effects, but in a less degree. We are not able, however, to look upon equitation as so certain a cure in consumption as Sydenham did; who says that riding on horseback is as much a specific for phthisis, as the Peruvian bark is for an ague.

Iodine and its compounds, and especially the iodide of potassium, have been much praised for their reputed efficacy in phthisis. Given in small doses, I believe that they often have a beneficial influence upon the general health. I wish I could tell you that I had ever known them work a cure of the manifested disease.

The oil obtained from the liver of the cod-fish—a substance formerly thought curative of chronic rheumatism—has of late been extensively administered, with unquestionable benefit, in strumous disorders, and especially in pulmonary phthisis. It is not directed against any particular symptom: but appears, in a much greater degree than any other drug that I know of, to be antagonistic of the consuming power of the disease. Unlike many of the oils, it does not generally purge. One of its most obvious and frequent effects is that of hindering the waste of the fatty tissues of the body: and even of promoting, by the excessive supply of that nutriment, a new de-

posit of adipous matter. The patient recovers flesh and weight, resumes a healthier aspect, and acknowledges sensations of returning strength and comfort. Meanwhile his cough is mitigated, he expectorates less, his pulse is reduced in frequency, hectic symptoms disappear, and the auscultatory signs declare a corresponding change for the better in the diseased lung. As bearing upon these ascertained facts, I would direct your attention to some interesting observations by Dr. John Hughes Bennett (to whom we are indebted for the introduction of the oil into this country as a remedy for phthisis), upon the *structural relation of oil and albumen in the animal economy*. They are contained in a paper read before the Royal Society of Edinburgh; and published in the *Monthly Journal of Medical Science* for September, 1847. Dr. Bennett shows that the proper nutrition and healthy organization of the body depend upon the maintenance of a certain relation between the oily and the albuminous principles which enter into its composition: and that in numerous forms of disease, the excess or defect of one or the other of these principles may be distinctly traced. "Tubercle," he remarks, "is a product varying much in constitution, but most frequently composed of an amorphous molecular matter, little altered by the addition of æther, and rendered more transparent by acetic acid." The whole range of morbid changes denominated tubercular, belongs to the class in which there is an excess of the albuminous, and a deficiency of the oleaginous principle. In these speculations do we not obtain some glimpse of the way in which the cod's-liver oil (and other oils, perhaps), may tend to correct, or to keep in check, the strumous disposition? Whatever may be its *modus operandi*, I have often been surprised as well as gratified by the improvement that has followed the use of this remedy in consumptive patients. I believe that the earlier it is resorted to, the better; but in every stage of the disease its healing power has been fully ascertained. In many advanced cases it does no good at all: in some its restorative effect is really wonderful. The proper dose is from two drachms to half an ounce, three times daily. To avoid the risk of blunting the natural appetite, I am in the habit of directing that the oil be taken at bed-time, and soon after each of the two principal meals of the day; in other words, as long as possible before the meal next ensuing. Of the various kinds of oil in use, that which is the purest, that which is obtained by the simplest methods from the fresh liver of the healthy cod-fish, is not only the least nauseous, but in my opinion the most remediate also. It is not so nauseous, patients tell me, as might be supposed.

Upon children, or others, affected with scrofulous swellings of the cervical glands, the beneficial influence of the cod's-liver oil is perhaps still more certain and conspicuous.

Often — too often — all that we can attempt to do is to relieve the most urgent or distressing symptoms: and to make easier the patient's decline. One symptom which is both distressing and weakening is the nocturnal perspiration. The common remedy for this is the dilute sulphuric acid: and a very good remedy it is, but it is not equally adapted to all cases. If the bowels are costive — or if the bowels have not, as they often have, a tendency to be relaxed — then the sulphuric acid may be freely given: and it will often have very good results. It may be exhibited three or four times a day, in doses of from twelve to twenty minims. But when this fails, or when the bowels are irritable and will not bear it, we must have recourse to other means. One of these is sponging the surface of the body, at bed-time, or before the patient settles himself for the night, with tepid vinegar and water: using twice as much water as vinegar. And if the bowels are at the same time purged, I find the compound kino powder of the Pharmacopœia an admirable medicine. It certainly has much power over the perspiration; and it has these further advantages, that (containing opium) it tends to control the diarrhoea, and to calm the cough.

Steel is another substance which exercises a marked influence sometimes over the hectic fever. It was its efficacy in this way that gave celebrity to the famous antihetic mixture of Dr. Griffith, the *Mistura Ferri Composita* of the Pharmacopœia. Certain it is, that when steel is borne in the advanced stage of consumption, it often does a world of temporary good; — but in many cases it is *not* borne well. It increases the cough, occasions headache, and heat of skin, and distresses instead of relieving the patient. Nor is it always easy to say beforehand, whether it is *likely* to suit the case or not. I apprehend it will at length be found most applicable to the unmixed forms — the uninflamatory forms, that is — of phthisis. I have frequently,

however, succeeded in checking the wasting sweats by the *Tinctura Ferri Murialis*, given in doses of twenty minims thrice a day, after other expedients had failed me.

When the cough is very troublesome, and especially when it breaks the patient's rest at night, we must endeavour to quiet it; and there is no drug, I fear, that we can depend upon for that purpose, but opium. The old paregoric has been, and is, a favourite form for giving opium to appease cough; and old-fashioned apothecaries will tell you that the alteration which was made by leaving the aniseed out of this compound tincture of camphor, in the last Pharmacopœia but one, impaired its efficacy. Whether it was so or not I cannot tell; but Dr. Prout is of opinion that *aniseed* has considerable power in allaying the irritation on which the cough depends. He infuses three drachms, or half an ounce, of the bruised seeds in half a pint of distilled water at a temperature not exceeding 120°; and lets it stand till it is cold. On his strong recommendation I have tried this, as a vehicle for paregoric, when the same dose in other vehicles had failed; and I must say, that it has frequently been followed by a marked abatement of the frequency and violence of the cough. The aniseed is restored in the paregoric of the last Pharmacopœia, that of 1836. Hydrocyanic acid has sometimes a very soothing effect upon this harassing symptom. However, at last, opium will be found our sheet-anchor, not merely for the cough, but for the diarrhœa which is so seldom absent in the latter periods of phthisis. The diarrhœa depends, as I have told you, upon an ulcerated state of the bowels. In those cases in which it could scarcely be kept in check at all, I have always found very extensive ulceration in the large intestines: but the diseased condition is often seated higher up, in the ileum or jejunum. The Physicians to the Brompton Hospital commend bismuth as a remedy for this symptom: the tinctures of catechu and of rhatany are also of much service, combined with laudanum and with the officinal chalk mixture:—or a few grains of the *confectio opii* may be given in peppermint water, after every loose evacuation:—or in obstinate cases, a pill composed of a quarter of a grain of the sulphate of copper, and the same quantity of opium, will often answer well, though it sometimes gripes. I mention these several expedients, for you will often require them all. The injection of a small quantity of starch, as much as the rectum will receive and retain, with ten or twenty drops of laudanum, generally affords the patient most sensible comfort; and suspends the further action of the bowels for a considerable time.

These, I think, are the principal means by which we may endeavour to smooth the pillow of the patient dying of consumption. Sometimes very little pain or distress is felt at all, from first to last; the intellect remains free, and the patients are proverbially sanguine about the issue of their disorder. In other cases, do what we will, the patient suffers greatly. One harassing incidental combination of symptoms is nausea and vomiting. I should have stated before, that when, in phthisis, these symptoms last long, and are accompanied by pain and tenderness of the epigastrium, they denote, almost always, a thinned and softened condition of the mucous membrane of the stomach. They may be alleviated by a leech or two—by a blister—by the effervescing draught: or the prussic acid may be used; that is a medicine which certainly tranquillizes an irritable stomach, as it now and then allays an urgent cough. Sometimes, again, the bones of the miserable patient are laid bare, in consequence of pressure upon parts in which the circulation is already very feeble. We cover these with soap-plaster; take off the pressure by arranging cushions; or, what is much the best of all, we put the patient upon the water-bed, invented by Dr. Arnott.

LECTURE LVIII.

Melanosis of the Lung; true, and spurious. Accidental intrusion of solid substances into the air-passages.

I YESTERDAY adverted to certain callings which are unhealthy for various reasons, and among the rest for this;—that the work-people engaged in them breathe habitually an atmosphere loaded with particles of matter which clog or irritate the pulmonary tissues. There is one morbid condition, so produced, which hitherto, or till lately, has scarcely been mentioned by writers on disease, but which deserves a moment's attention; for although it is very uncommon in many parts of this country, it is by no means rare in some others. The texture of the lungs is spoiled by matters carried in with the air, in the acts of breathing. This morbid state has been called *spurious melanosis*. The lungs are found after death to be throughout of a black colour, more or less uniform. Sometimes the pulmonary substance is dry and friable, as well as black; sometimes moist, œdematous, infiltrated with an inky fluid; not unfrequently broken down into irregular cavities of various sizes; and these cavities are often full of the same black liquor.

You are not to confound these appearances, when you happen to meet with them—(and as you will probably scatter yourselves, some here and some there, over various parts of the kingdom, some of you are very likely to meet with them)—you must avoid, I say, mistaking these black appearances and products, for *true melanosis*. The disease so denominated is a singular one. It was first fully described and named by Laennec in 1806. It consists in a morbid product, presenting a black or deep brown colour of various degrees of intensity, moist generally, unorganized, and differing in the form it assumes, and in its consistence, according to circumstances. I shall take this opportunity, for I am not likely to have a better, to tell you the little that has been ascertained in regard to this kind of disease; and having done so, I shall revert to a short account of *spurious melanosis*.

These black deposits take place most frequently of all in the areolar tissue, and in the adipous tissue: and they occur in greater abundance, and in larger masses, according as these reticular tissues are more plentiful, and more lax. They are met with also in the compound organs of the body; especially in the liver. Less frequently in the lungs. Sometimes in the eye. Occasionally in the brain. The serous membranes are obnoxious to the same kind of disease; the mucous very little so. The black or dark-coloured matter may also exist, in a liquid condition, in the natural cavities of the body. And lastly, the melanotic material is sometimes mixed up with scirrhus and brain-like malignant tumours.

With respect to the shapes in which it appears—it is sometimes dotted, the surfaces affected by it looking as if they had been thickly sprinkled over with coal-dust or soot. But more commonly melanosis assumes the form of solid tumours, of variable magnitude. These tumours are largest, where reticular tissue is most loose and abundant. They may be no bigger than a pin's head, or they may be as large as a man's head. Masses of this kind have been found in the horse, weighing as much as six-and-thirty pounds. In the human subject they may attain the size of an orange. These large tumours (like large pulmonary tubercles) are usually formed by the union and agglomeration of several smaller ones, and hence they have generally a lobulated surface: while the shape of the separate smaller tumours is mostly spherical. Sometimes the areolar tissue lying around the melanotic masses is condensed into a kind of cyst: more generally the black matter is in naked contact with the tissue, whatever that may be, in which it is lodged.

From the serous surfaces, especially from the pleura and peritoneum, knobs of a dark colour are seen in some instances to project; in others, round tumours, as big

FIG. 74.

Melanotic deposit in cells of an engorged lung. Some of the cells contain oil-drops.

as peas, or cherries, hang from these surfaces by a sort of peduncle. The omentum is a common *habitat* of melanotic tumours.

Occasionally, I say, the black matter is found spread in a continuous layer upon the serous membranes; or is collected in a liquid state in their cavities. But this, compared with the occurrence of solid tumours, is rare.

When this remarkable disease is met with in one tissue or organ of the body, it is met with in others. It is never confined to one part, but pervades several: resembling in this respect both the serofulous matter which constitutes tubercle; and the matter of cancer. Müller indeed considers melanosis to be a species or variety of carcinoma.

Scattered notices of these singular and striking changes in the animal frame occur in the works of Morgagni and of Haller; but since the period when Laennec first drew the special attention of the profession to the subject, the black matter has been carefully analysed by several expert chemists. Without going into any tiresome detail, which you would scarcely remember, as to its exact composition, it is interesting to know that it is very like that of the blood: and no doubt the material is somehow deposited from the blood. Very little, however, has been ascertained about its primary origin and cause. Some have supposed that the melanotic matter is analogous to the natural pigments which are found in the animal economy; all of which are known to be rich in carbon. It is a curious fact that the disease has been more often observed in white or grey horses than in others. (I should tell you that the complaint is not at all uncommon in various quadrupeds: examples of it have been noted in the horse, ox, dog, cat, rabbit, rat, and mouse.) It has been conjectured that, in white animals, the colouring matter of the surface, and of the hair, has been diverted, by some morbid process, from its proper locality. But the very same disorder occurs also, though not so often, in dark, or bay, horses and cows: and certain pathologists imagine that in these cases there has been an undue accumulation, in the blood, of the carbon which is destined to colour different parts. In the one case, you see, they hold that the pigment is misplaced; in the other that it is excessive. What value these speculations as to the nature and origin of the disease may possess, time alone can determine.

When the tumours are divided, and moist, or when they are rendered moist by admixture with water, they freely impart the colouring matter; staining white paper, and blackening one's fingers, just as Indian ink might do. The disease most frequently happens, when it happens at all, in the decline of life.

The changes to which the melanotic tumours are liable, are very much like the changes which tubercular matter is apt to undergo. In certain situations, where the secreted black material is subject to pressure, and is poured out in a soft consistence, the watery parts are sometimes absorbed, and the mass becomes hard and firm. On the other hand, the pressure occasioned by the tumour sometimes provokes inflammation in the tissues surrounding it; and then it is liable to be broken down, exactly in the same way as that in which tubercles soften prior to their expulsion from the lungs.

The injurious effects of these collections of black matter arise from the pressure they occasion; and they may evidently thus cause pain, irritation, ulceration; and, according to their situation, number, and extent, they may materially interfere with important functions. And in this manner they do, in fact, at length destroy life.

There are no symptoms, that I know of, distinctive of this disease, except the appearance of the black masses upon the surface of the body. Nor can I pretend to point out to you any cure for it, when it has been ascertained to exist.

Yet it is right that you should be aware of what pathologists have learned respecting this curious morbid state; although that be little, and not very satisfactory. And I have introduced this brief consideration of melanosis here, somewhat irregularly perhaps, to enable you to distinguish from it that pulmonary disease to which I referred in the outset of the lecture, and to which I shall now return. This, I say, has been called *spurious melanosis*: and it has doubtless been mistaken for the specific disease of which I have just given you a sketch; for *real* melanosis.

It is, however, a very different affection.

Laennec had conjectured that certain kinds of black discoloration of the lungs were of extraneous origin; were owing to the introduction of black matters from without in the process of respiration: and Mr. Pearson, in this country, had thrown out the same idea. But that this was actually the case was first ascertained in Edinburgh.

Dr. J. C. Gregory had a patient who died in the infirmary of that city, and whose lungs exhibited the following appearances:—They both presented one uniform black carbonaceous colour, which pervaded every part of their substance. The right lung was broken down, in its upper and middle lobes, into irregular cavities; and the walls of these cavities were black; and they contained a considerable quantity of black liquid like ink. Portions of the pulmonary substance were dense, hepatized, and friable. The rest of this lung was œdematous; and when the serum which rendered it thus œdematous was pressed out, it also, the serum I mean, was quite black. The left lung was infiltrated, in the same manner, with black serum. No tubercles could be detected. The bronchial glands were not enlarged, but they were stained of the same sable hue as the substance of the lungs. No other organ of the body presented any trace of this black discoloration.

Dr. Christison, who is known to be a very exact and able chemist, undertook an analysis of the black matter contained in the serum expressed from these lungs. I shall not follow out the details of his researches (you may read them at length in the 109th number of the *Edinburgh Medical and Surgical Journal*), but content myself with stating their result. And I may state it in Dr. Christison's own words. "In the product of this experiment (he says) it is scarcely possible not to recognise the ordinary products of the distillation of coal. A gas of the same quality was procured, and likewise a naphthous fluid holding in solution a crystalline principle, analogous to, if not identified with, naphthaline."

Now the man, whose lungs presented the appearance I have described, had, for the last ten or twelve years of his life, been employed in the coal-mines at Dalkeith. He had been exposed therefore to the habitual inhalation of coal-dust into his lungs in breathing: and taking this circumstance in conjunction with the result of the analysis of the black matter contained in the lungs, and nowhere else throughout the body, we cannot doubt that the carbonaceous substance so abundant in these organs was introduced from without. In truth we have now a large amount of evidence in proof that it must have been so. In the twenty-first volume of the *Medico-Chirurgical Transactions*, Dr. William Thomson has recorded the results of extensive inquiry into the subject. Thus he gives ten examples of black sputa going along with pulmonary symptoms during life, and of black infiltration of the lungs discovered after death; and of the ten persons who were the subjects of these observations, nine had been engaged in working coal-mines, and the tenth was a moulder at the Carron iron-works. He gives also six cases of black infiltration of the lungs, all occurring in persons exposed to the inhalation of carbonaceous matters (one of them was an engineer, and the others were all colliers); but in these six cases there had been no black expectoration noticed during life.

That such carbonaceous particles, floating in the atmosphere, may be, and must be, and actually are, drawn into the lungs during inspiration, no one who has been long in this smoky town can doubt. Many persons remark that they expectorate during winter, and while in London, a little mass or two of dark grey, dirty mucus, every morning; but when in the country, and in the summer, the mucus so spat up is transparent and clean. So I have noticed, and pointed out to some of you, that the *crachoirs* of the patients in the hospital often bear witness that there has been during the previous twelve hours, one of our dense and dirty fogs, which come with an easterly wind, and bring with them a vast quantity of blacks, and soot, and smoke. Immediately after the prevalence of one of those filthy blankets of vapour, we find the contents of each of the little vessels given to the patients whose expectoration is kept for inspection, to be deeply tinged with black. And I had, in the year 1832, a patient whose sputa were remarkably loaded with dark matter. He came into the hospital complaining of cough, and of shortness of breath, and of a sensation at the lower part of the right side of the chest, as if it were pierced by needles; and he was spitting a considerable quantity of thick mucus, which was almost black. This colour never entirely left the expectoration while he remained in the hospital; but it very greatly diminished, in proportion as his ailments were relieved. Now this man was a stoker at one of the gas-works. And he attributed his illness, which had come on gradually, to the great alternations of heat and cold to which his occupation exposed him: and the blackness of the sputa he ascribed to the continual inhalation of coal-dust. And no doubt he was right.

It may seem strange, if the inhalation of atmospheric air loaded with minute particles of coal or other carbonaceous matter, be sufficient to produce this remarkable condition of the lungs, and the characteristic *black spit*, that the change, and its nature and cause, should not have been earlier made out: when we consider the vast number of men who are employed in our mines and collieries. It appears, however, that a great repugnance has existed, and probably still exists, among the labourers in the coal mines, to allowing their dead to be opened and examined. And it appears further that the peculiar state of the lungs which I have been speaking of is produced in a comparatively small number of those who are so employed. The precise cause why some are thus affected, and some are not, has yet to be discovered. Dr. Thomson has circulated among the medical men residing in the coal districts, a list of queries (which he gives in his paper), respecting various points of interest in relation to this pulmonary condition: and we may expect to obtain, by degrees, more exact information about it. I recommend it as an interesting subject of inquiry to such among you as may have opportunities of prosecuting it. It has been conjectured that the specific change takes place, in a marked degree, only in lungs that were previously unsound. It is a question whether the cavities met with in the pulmonary substance, in the fatal cases, were the result of the spurious melanosis; or of the expulsion of tubercular matter which had coexisted with, or preceded, the melanotic state. It is a curious circumstance that the black spit, as it is called in those districts, sometimes does not make its appearance until a considerable period has elapsed after the time when the labour in the coal mines was given up. Dr. Makellar, who has more recently described the disease as he met with it among the colliers in the Lothians, is of opinion that the blood becomes unnaturally loaded with carbon; and that when once a certain quantity of the black matter from without has been lodged in the pulmonary tissues, a disposing affinity is thereby created for the carbon in the blood, so that more and more of that substance continues to be deposited, even long after the patient has abandoned his occupation, and ceased to inhale the noxious atmosphere. Certainly this is a complaint that offers several interesting points of research, and requires further investigation.

You will remark that the spurious melanosis is distinguished from the true, by its occurrence in those persons only who are somehow exposed for a certain length of time to breathe an atmosphere which is largely encumbered with carbonaceous particles; whereas true melanosis may occur in any locality. The spurious discoloration never affects any other organs than the lungs and bronchial glands; the true black deposit of melanosis is never confined to a single organ or tissue. Moreover, the one disorder is absolutely beyond remedy; the other, as soon as its presence is rendered probable, by the black expectoration, and the pulmonary distress, may be mitigated, checked, perhaps gradually cured, by removing the patient from the operation of the exciting cause, and pursuing such other measures as the symptoms may seem to require. The distinction is not a matter therefore of mere curiosity: it bears upon the treatment to be followed, which is our proper business. It is connected also with medical police or hygiene, which we should all of us cultivate as extensively as we may; as a science intimately related to our strictly professional pursuits, and to the welfare of the community.

Other forms of disease, unquestionably cancerous, occasionally infest the lungs. Their chief symptoms, when the malady does not reach the surface of the body, result from the pressure which the carcinomatous masses exercise on the parts in their neighbourhood. I shall postpone a more particular consideration of these effects of intra-thoracic pressure, until I come to aneurismal tumours, which have a similar mechanical influence.

There is yet another affection of the breath-machine, to which I must briefly direct your attention: a casualty that is apt to befall the air-tubes. I said nothing of this, indeed, last year; but having since witnessed an example of the accident to which I allude—the entrance, namely, of some solid substance into the windpipe—I have thus been reminded of my former omission, and taught at the same time the necessity that every medical man should have well considered such cases. I was taken to Kentish Town, in the autumn (1837), by a professional friend, to see a child, into

whose trachea a small nail, what is commonly called a *tack*, was thought to have passed. When I saw the boy, he seemed to have nothing the matter with him : but he had been subject, ever since the accident, to paroxysms of most violent choking cough ; alarming the parents and his attendants for his life. There was good reason for concluding that the nail, which was missing, and which he said he had *swallowed*, had really got into the windpipe, and was still there, or in the lungs ; and the question was much discussed, what ought to be done in such a case ? The result was, that nothing was done : but that after the lapse of several weeks, the nail was at length coughed up.

Now there are some interesting points arising out of this sort of mischance. The instance I have just referred to will probably be published ; and therefore I dwell upon it the less. Dr. Stokes has devoted a short chapter to the consideration of foreign bodies in the air-passages : and examples of that accident are more common than you might suppose.

It is, at first sight, a surprising circumstance, that a solid body of any considerable magnitude (a molar tooth for instance), should be able to pass at all through the narrow chink of the glottis. But, supposing the chink to be plugged by the sudden entrance of a passing substance, just at the commencement of a forcible endeavour to inspire, when, of course, the opening is at the widest, that substance must necessarily sustain, as the chest expands, a strong degree of pressure from the external atmosphere : strong enough, often, to force it through. If you cork a bottle that contains air only, and sink it sufficiently deep in the sea, the pressure of the water will push the cork into the bottle. The condition of the lungs, in the case supposed, and the condition of the bottle, are analogous. A vacuum beyond the plug is attempted by the act of inspiring, and obviated by the displacement of the plug inwards. There are no such powerful forces called into action to drive the intruding substance out again.

The matters which have been actually thus caught in the rima glottidis, and forced through, are, as you might almost expect, oddly various in kind. Morsels of food : the stones of fruit ; of these there are many instances : teeth ; three such cases are referred to by Dr. Stokes : portions of bone : pebbles : a piece of money : a nut : a nut-shell : a button : a musket-ball : a large shot : a fragment of nutmeg : iron nails : kidney-beans : ears of grass or corn ; of these, four examples at least have been noticed ; one is mentioned by Dr. Stokes, two are recorded in the *Gazette Médicale*, and I show you a monument of the fourth, in this interesting preparation, for the history of which I am indebted to Mr. Mayo. The young son of an English nobleman was riding in a carriage, in or near Paris, and had an ear of rye in his mouth. The carriage made a sudden jolt, and the ear of corn disappeared. Little was thought about this at the time : but soon afterwards symptoms of pulmonary irritation set in, attended with hectic fever, and with the most fetid expectoration. The boy gradually sank. The ear of rye lay, as you may perceive, in an abscess which was common to the right lung and to the liver, through the diaphragm.

If any of you have tried the boyish trick of slipping beneath your wristband an ear of bearded corn, you will have no difficulty in understanding how and why, with every movement of the parts in contact with it, the ear will travel onwards ; and how improbable it is that such a substance should ever be expelled from the lungs by coughing. Yet, in one of the cases recorded in the *Gazette Médicale*, by a physician whose sister was the subject of the accident, an ear of barley was so rejected, seven years after its entrance. During that long period she had suffered repeated attacks of copious hæmoptysis. Her recovery was perfect.

The very enumeration which I have just made may convince you that the accident is not a very unfrequent one ; and it is more than probable that fatal cases happen, the nature of which escapes detection.

The results of the accident are various also.

In the first place, it sometimes causes speedy death by apnœa.

2dly. It may be followed by inflammation of the lung, and perhaps abscess ; and so destroy life.

3dly. Death may ensue, after symptoms resembling those of chronic phthisis.

4thly. The "foreign body," as we oddly enough call it, may be expelled through the glottis, after a variable period of time. Sometimes, yet not always, its expulsion

is the condition and the harbinger of the patient's recovery; but he is never safe while it remains.

Death may take place in a few seconds when the substance sticks in the glottis. Death *has* occurred within three days, when the substance had passed the glottis; and in eleven days when it had reached the lung. The intruding piece of matter has escaped, through the natural passages, after remaining imprisoned for seventeen years. In that case, the patient died, hectic and emaciated, a year and half afterwards.

It may be worth our while to consider these particulars somewhat more closely; and to inquire what, in different cases, becomes of the foreign body which thus, to use a common phrase, "goes the wrong way;" and what the symptoms are to which it may give rise.

First, then, I say, it may get wedged in the slit of the glottis, and produce immediate suffocation. I mentioned, before, the frequency of this kind of death by misadventure. If you are summoned to any one whom you find comatose, or apparently just dead, and you learn that he had been suddenly attacked with choking during a meal, lose no time in examining his pharynx and gullet. You may chance to save a life so. The accident often happens to persons who are drunk. No doubt it happens oftener than we are aware of. The attack is very likely to be mistaken for an apoplectic seizure.

In these cases of sudden choking, the morsel of food is not always caught in the rima glottidis. If it be large enough to stick fast in the *pharynx*, it may provoke, through a reflex action, an abiding spasm of the little laryngeal muscles, and so produce death by apnoea. The remedy for such an emergency, as Dr. Marshall Hall truly observes, must be *immediate*: and this is what he tells us should be done.

"Pressure being made on the abdomen, to prevent the descent of the diaphragm, a forcible blow should be made by the flat hand on the thorax. The effect of this is to induce an effort similar to that of expiration; the larynx being closed, œsophageal vomiting takes place, and the morsel is dislodged.

"If this plan fail, not an instant being lost, the pressure should be kept up on the abdomen, the finger should be introduced into the throat, and the same smart and forcible blow made on the thorax as before. By the irritation of the fauces the cardia is opened, and by the blow on the thorax (firm pressure being made on the abdomen) an effort similar to that of expiration, with a closed larynx, is made, and a direct vomiting ensues, and the morsel of food is carried away."

2ndly. The substance, if small, may, after it has passed the chink, remain in the larynx; entangled in its ventricles, or between the chordæ vocales. In that case it usually occasions very severe laryngeal symptoms—spasmodic gasping cough, choking sensations, croupy respiration, and pain in the larynx—symptoms which harass the patients without intermission, until death ensues, or until the substance is driven upwards into the pharynx, or drops downwards into the windpipe. There is, however, one instance on record, in which a piece of gold was lodged for years in the ventricles of the larynx, without these distressing consequences.

3rdly. Having passed the upper part of the larynx, it may stop, and become fixed beneath the cricoid cartilage, or in the trachea. In these situations, unless it quite blocks up the passage, its presence may be productive of but little distress. A wheezing or croupy sound during one or both of the movements of respiration, and some degree of pain and tenderness of the part where the substance was lodged, have constituted all the evidence of its position in the air-passages, in more than one instance. A very singular and whimsical case of this kind, related by Professor Macnamara, is referred to by Dr. Stokes. A boy had made a whistle, by perforating a plumstone, and extracting the kernel. This, during a strong inspiration, passed from between his lips, through the glottis, and became fixed transversely in the larynx. So little inconvenience did it create, that the boy, finding that he still whistled as he breathed, went about for some hours, pleased to display this new accomplishment. For three days he continued to occupy himself in his childish amusements, suffering now and then a seizure of suffocating cough. He was then taken to the Meath hospital. He had no pain in deglutition; but he said that when the cough was severe, it caused pain in his throat. He had also uneasiness in the epigastrium, a bloated countenance, and a frequent pulse. The chest sounded well on percussion,

and the vesicular murmur was natural. The fits of coughing were followed by white frothy expectoration. Laryngotomy was performed; but during the struggle and the convulsive cough which took place when the opening was made, the stone (so the patient declared) was coughed up, and swallowed. The symptoms were relieved; and the whistling ceased. But it was found that, as the wound healed, the distress and the whistling sound returned; which showed that the stone lay above the opening; and that the disappearance of the symptoms had been owing, not to its dislodgment, but to the admission of air below the point where it was fixed. Soon after this, however, it changed its place, passed down into the right bronchus, and then up again towards the larynx. By a second operation it was extracted; and the lad recovered without any bad symptom.

4thly. The substance may get beyond the trachea, into one of the bronchi, and stay there. And it is a very curious fact, and one which has evident importance in respect of diagnosis, that it is almost always the *right* bronchus which the substance enters. Dr. Stokes has explained why it is so. The septum that divides the extremity of the trachea into two branches is not placed in the middle of the channel, but decidedly towards the left; so that any solid body falling down through the wind-pipe, is naturally directed into the right bronchus. Perhaps this tendency is aided by the more vertical direction, and by the somewhat greater capacity of that tube, compared with its fellow. Now you will readily apprehend what sort of symptoms would be likely to result from the impaction of a solid body in either of the primary bronchi. It would be very apt to excite inflammation of the corresponding lung, which inflammation would reveal itself by its proper signs; but it would produce peculiar auscultatory phenomena, prior to and independent of such inflammation. It would prevent, partially or altogether, the entrance of air into the lung of that side. Hence, when we have other reasons for thinking that a solid body has passed the glottis, if we find the vesicular murmur suspended or enfeebled in one lung, while percussion gives out its usual clear sound, we may conclude that the intruder is lodged in the bronchus belonging to that lung. It seems not improbable that collapse of a portion of the lung may sometimes result from its presence there. This would modify the symptoms; but still the same conclusion would be warrantable from them.

Dr. Stokes believes, and his opinion is fortified by his own experience on the subject, that smooth bodies (beans or shots, for example), are more calculated than such as are rugged and uneven to cause urgent distress when impacted in one of the bronchi; inasmuch as they more completely plug and obstruct the tube, thereby depriving the patient at once of the use of half his lungs. An irregular substance, which can neither seal the passage up, nor be closely grasped by its spasmodic contraction, will probably occasion less dyspnoea, and at the same time will be less likely to be dislodged by the effort of expiration. Under these circumstances we look for more chronic symptoms.

5thly, and lastly. The intruding substance may not be fixed anywhere, but may shift its place from time to time; and this, in fact, is what most frequently happens: and when it does happen, it gives rise to a very striking and distinctive series of symptoms. Paroxysms of suffocating cough and extreme distress, when the substance is driven up into or near the larynx; with intervals of comparative quiet, and sometimes indeed of apparent health, when it subsides into the trachea or bronchi. But during these intervals, the signs that sometimes mark its situation in those tubes may perhaps be discoverable.

There are, then, a set of general symptoms, which lead us to believe, or to suspect, that some solid body has entered the air-passages: and there are other sets of particular symptoms, which inform us, with more or less certainty, whereabouts it is fixed, or that it is not fixed at all. A person, previously in good health, is seized with violent cough and choking dyspnoea, suddenly, during a meal, or while he had in his mouth some loose substance, which he fancied he has swallowed. This is a sufficient clue to the probable nature of the case: and we next inquire for a sense of soreness in the windpipe, and wheezing respiration; for signs of bronchitis or of pneumonia, especially in the right lung; for signs of obstruction of the bronchus on one side, and especially on the right side; or for alternations of suffocating cough, with intervals of

outward calm. In the last case, we may expect to find the bronchus unstopped during the periods of laryngeal irritation; and *vice versâ*.

When we know that a solid body has been entrapped in the air-tubes, our business is plain; there is no room, in my opinion, for hesitation: we must let the substance out through an artificial wicket. There is danger, so long as it remains in these vital passages, of speedy suffocation; of fatal damage to the larynx, or to the lungs; of cerebral mischief during the violent paroxysms of coughing. Convulsions and apoplexy have, under such circumstances, actually occurred. Against these perils there is no security, except in the early performance of tracheotomy. If the included substance be loose and smooth it will presently be shot forth at the new orifice; if it be fixed, or angular, it may generally be extricated by a skilful and delicate hand.

Even while this sheet has been passing under the press (May, 1843), another instance has occurred of the same accident, and excited a degree of anxious interest in the public mind, scarcely less than is accorded to a royal illness. It befell a gentleman whose name was previously famous. Mr. Brunel, in amusing the children of a friend with some tricks of legerdemain, put a half-sovereign into his mouth; and the coin slipped, as from its size and shape it might easily do, through the chink of the glottis. It seems to have occasioned no very urgent distress. The patient was made aware, by some internal sensation, that it lay towards the right side. After more than three weeks had passed, the trachea was opened: but the piece of money did not come forth. Probably its weight prevented its being driven up and down the windpipe; and when it laid edgeways, its form did not oppose much impediment to the breath. The same weight, however, brought it back to the larynx whenever Mr. Brunel placed himself with his head downwards. In some of these experiments, coming crossways I suppose, it produced most violent cough, and feelings of impending suffocation: but in a final and happier trial, at the end of six weeks, it dropped out again, through the natural passage — just as a coin may sometimes, by good luck, be shaken out of a box through a slit in the lid.

A still more recent example of a similar mixture of bad and good fortune has been recorded by Dr. James Duncan in the *Northern Journal of Medicine*. A man was amusing himself with tossing up a shilling, and catching it in his mouth. Suddenly it fell into his larynx, and produced violent cough and severe dyspnoea, which gradually subsided. The difficulty of breathing returned in paroxysms, upon his making a deep inspiration, or after certain movements of the body. When the larynx was compressed externally, the man felt that the coin was lying opposite to the cricoid cartilage. He was now held with his head downwards by three strong men, was shaken once or twice in that position, and his larynx was moved from side to side, when lo! the shilling re-entered his mouth, and dropped out upon the floor. During this process he suffered neither cough nor dyspnoea.

An almost exact counterpart of this case has since been communicated to me by Dr. G. B. Halford. In the year 1852, when that gentleman was house-surgeon to the Westminster hospital, a man was admitted, about noon, who stated that on the previous evening, while entertaining his children by throwing a shilling into the air and attempting to catch it in his mouth, the shilling slipped into his windpipe. He had been to several medical men, and had taken emetic after emetic in vain. The shilling could be distinctly felt opposite the crico-thyroid membrane. The man's voice was reduced to a whisper. Dr. Halford "directed the porters of the hospital to turn him upside down in the corner of the surgery, when, after several expiratory efforts, the shilling rolled out of his mouth."

Notwithstanding the speedy and easy dislodgement of the coins in these instances, it may be prudent and requisite, in less fortunate cases, when the piece of money does not fall, at first, in the right direction, to lessen the risk of suffocating cough, by making an artificial opening in the trachea. If the substance be within reach, it may be then plucked forth with forceps: if not, the safety valve thus established will render

the inversion of the patient's body less distressing and less hazardous; and allow it to be repeated until it shall prove successful.

For Mr. Brunel's convenience a sort of platform was constructed, moveable upon a central hinge. To this platform he was bound in the prone position, by a broad strap passing across his shoulders; and then his head was lowered until the platform was brought to an angle of about 80 degrees with the horizon. This did not succeed until after the opening was made in his windpipe.

[For a full account of everything connected with the subject of foreign bodies in the air-passages, and the treatment best adapted for the relief of the patient, the reader is referred to the very able treatise of Dr. Samuel D. Gross, *Philada.*, 1855.—C.]

LECTURE LIX.

Diseases of the Heart: usually partial. Changes in its Muscular Texture. Mechanism of those Changes. Natural dimensions of the Heart. Natural Sounds. Modifications of these by Disease. Review of the Physical and General Signs that accompany Cardiac Disease.

You will perhaps accuse me, gentlemen, of a disposition to magnify the importance of every new class of diseases at which we arrive, in our survey of the morbid conditions of the various parts of the body in succession. There are few complaints, in truth, which are not important; either from the discomfort to which they give rise, or from their tendency to abbreviate the span of human existence. Yet of the strictly vital organs the derangements are necessarily the most perilous; and therefore, to us, the most interesting. Two props of the tripod of life we have passed in review, and seen how they may be weakened, and how they may fail altogether. The office of the *heart* is not less essential to life and health, than that of the brain, or of the lungs. The well-being of every portion of the frame depends upon its being duly supplied with healthy arterial blood, and duly relieved of that which has become venous: and this supply and relief require that the central organ of the circulation should be sound in its structure, and perfect in its working. But it is frequently otherwise. I can remember, indeed, the time when disease of the heart was thought to be a very rare thing; but it is now well-known to be one of the commonest of disorders, and it connects itself with a variety of other affections, with which it was formerly supposed to have no relation.

Like other organs that are complex of structure and formed of different tissues, the heart is subject to *partial* disease. Its lining membrane alone may, in the first instance, become the seat of inflammation, with its various effects; or its investing membrane only may undergo morbid alterations; or the muscular substance that constitutes the organ itself may be gradually changed in its qualities, in its bulk, or in its proportions.

But the morbid conditions of the investing and lining membranes do not always, or immediately, compromise the life of the patient. They are fatal at length, in ninety-nine cases out of a hundred, through the alterations to which they lead in the muscle wherewith they are connected. It may be practically useful therefore to consider, first, these ultimate morbid states which are incompatible with the continuance of life; and then to trace them back to the next link in the chain of their causes, which will be found, in a very great number of instances, to consist in some antecedent morbid state of the exterior or of the interior membrane.

The heart, you know, is a living forcing-pump; a hollow muscular engine, with its chambers and their valved outlets, its contractile walls and their strength and thickness, so admirably adjusted, that the healthy balance of the circulation is continually

maintained, under many varying outward influences and inward emotions which tend to disturb it. In treating of diseases of the heart we have to consider, therefore, the modes in which its mechanism may be spoiled or deranged; and the effects of such derangements.

Not only the component tissues, but different portions also of the organ may be separately diseased. It seldom happens, indeed, that the whole heart is affected; although that is probably the vulgar belief. The left side is much more obnoxious to morbid changes than the right: and when both sides are implicated, the alteration is almost always more decided and conspicuous in the left than in the right chambers.

In the rapid sketch which I attempted of general pathology, in the outset of the course, I pointed out the various kinds of alterations to which the tissues and organs of the body, and therefore the heart among the rest, are subject. One or more of the chambers of the heart, you will remember may become larger or smaller than is natural; or have their walls increased or diminished in thickness, and consequently in power; or one or more of its outlets and orifices of communication may be widened or contracted: and the purposes and function of the organ will be more or less impaired by such changes.

In order, then, to have a clear conception of cardiac disease, it is necessary to analyse it, and to investigate the derangements of the several parts of the heart. And I begin with *hypertrophy*; augmentation of bulk in its muscular substance. And I must first of all define one or two phrases which are current among pathologists in respect to this condition.

The muscular tissue of one, or more, of the chambers of the heart may become thicker and stronger than natural, while the capacity of that chamber, or of those chambers, remains unaltered. The hypertrophy in that case is said to be *simple*.

But, while the muscular parietes are thickened, the corresponding chamber may become unnaturally large. This constitutes the *active aneurism of the heart* of Corvisart, the *eccentric hypertrophy* of more modern writers.

On the other hand, it has been supposed that the capacity of a cavity of the heart may diminish in size as its walls increase in thickness: that the hypertrophy may take place *at the expense* (as it were) of the chamber. This has been called *concentric hypertrophy*.

Now, of these three reputed forms of hypertrophy, considered in their relation to *disease*, two only, the simple and the eccentric, have any real existence. The third, or concentric form, never occurs, I believe, except as a congenital malformation. And of the two genuine species of hypertrophy, the eccentric, which is plainly a compound affection, consisting of *hypertrophy with dilatation*, is much the most common. The reason of this is to be found in the physical cause of the morbid condition, in most instances. The physical cause, in nineteen cases out of twenty, is some obstacle, mechanical or virtual, to the

Hypertrophy of the left ventricle. From a specimen in Dr. Gross' collection.

perfect accomplishment of the function of the chamber; some obstruction opposed to the free and thorough exit of the blood from it; or something which hinders the easy play of the organ. Hence, in the first place, a gradual yielding, or tendency to yield, in the sides of the affected chamber, from the continual and unwarmed pressure of the accumulated blood against them: and in the second place, a *striving* action of the muscle to overcome the hindrance, or to counterbalance the obstacle; and consequently, according to the law formerly announced, an augmentation in the bulk of the muscle whereof the function is thus increased. If the hypertrophy, which is the result of a truly conservative process, keep pace exactly with the amount of the obstacle and *exactly balance* it, no dilatation happens, or next to none. But this is comparatively seldom the case. According to the principles of mechanics, a little distension of the spheroidal cavity must require an increase of force to propel from

it a given quantity of blood, in the same time, through a given discharging orifice. So that incipient dilatation becomes (in addition to the supposed obstacle) an efficient cause of hypertrophy: and the two, the dilatation and the hypertrophy, commonly make progress together.

Even when there is no mechanical impediment, incipient dilatation (and consequent hypertrophy) may spring from morbid conditions of the nutrient blood. In this way, as we shall see hereafter, eccentric hypertrophy does often arise, without any valvular fault or physical obstacle to account for it, from renal disease, whereby the due purification of the blood is prevented.

Cruveilhier appears to have been the first to reject *concentric hypertrophy* from the catalogue of cardiac diseases. The smallness of its cavity, with a proportional increased thickness of its walls, was regarded by him as a transient condition of the ventricle, depending upon the mode of death. He found these phenomena very strongly marked in the hearts of all those whose bodies he had examined after decapitation by the guillotine; "Les parois ventriculaires se touchaient dans tous leurs points." It is therefore his opinion that the hearts which had been thought, by others, to present examples of concentric hypertrophy, were in reality "hearts more or less hypertrophied, which death had surprised in all their energy of contractility."

This question has since been considered by Dr. Budd, in a communication to the Medical and Chirurgical Society, which you may read in the twenty-first volume of its *Transactions*. He has lately favoured me with a statement of his matured views upon the subject.

The semblance of concentric hypertrophy is most common in the left ventricle; and depends upon the ventricle being nearly empty at the time of death, and upon the corpse being examined while the heart is contracted by the *rigor mortis*. The fallacious appearance is accordingly noticed in cases where, from the manner of dying, the left ventricle, or the entire heart, contains but little blood, and where, from the muscular power not having been previously exhausted, the rigor mortis is of long duration.

"In all these concentrically hypertrophied hearts (writes Dr. Budd) the ventricle may be readily dilated by means of the fingers, and always dilates of itself when the rigor mortis goes off.

"In the published cases of concentric hypertrophy, in which there was no disease of the valves (I have given eight such cases in my paper, and could now add a long list to them), there were no signs, or only very slight signs, of disease of the heart, during the life-time of the patient. This circumstance is sufficient proof that the cavities of the heart in these cases could not have been during life permanently in the contracted state in which they were found after death. A left ventricle that could scarcely contain an almond (a common form of expression in the description of these cases) would surely have caused a great impediment to the circulation."

Moreover, concentric hypertrophy could answer no mechanical purpose; nor could its formation be accounted for on mechanical principles. But "concentric hypertrophy of a ventricle, in a high degree, with obstruction at its discharging orifice, and an extraordinary channel for the passage of the blood, occasionally exists as a congenital malformation; and in most cases, the right is the ventricle so affected."

To resume. Recollect that there may be two distinct kinds of physical cause of excessive action of the heart, and therefore of hypertrophy. In the one kind, there is some mechanical obstruction to the exit of the blood from one or more of the cavities; a constricted state of the *orifices*, is the most common condition. In the other kind, without any such mechanical bar or dam to the fluid, there is something to hinder the free and sufficient play of the organ; unhealthy blood perhaps it may be, or malposition of the heart. If the heart be pushed, for instance, out of its proper place and posture by effusion into the pleura, or by distortion of the chest, it will not work with the same ease as when all is perfect and symmetrical; and the unusual labour imposed upon it fully to execute its office, will lead to hypertrophy. The causes of hypertrophy may therefore be situated *within* the heart itself, or *without* and beyond it: but in all those cases in which the effect of the hindrance or obstacle is to *detain* the blood in one or more chambers, the hypertrophy will be likely to be accompanied by *dilatation*: and, generally speaking, the hypertrophy and dilatation result from disease in some part which lies *beyond* the affected chamber, in the order

of the circulation. Thus either a narrowing, or a dilatation of the aorta at its commencement, will tend to cause hypertrophy and dilatation of the left ventricle.

That *contraction* of the aorta, or of the aortic orifice, may have this consequence, you will have no difficulty in perceiving. The blood cannot so readily pass through the narrowed channel; hence it will tend to accumulate in undue quantity in the ventricle, and therefore to stretch and dilate it; and the increased muscular efforts necessary to drive the delayed blood onwards, tend also to thicken the muscle itself. But it may not be so obvious that *dilatation* of the mouth of the aorta—a wider channel of egress—would also virtually prove an obstacle to the emptying of the ventricle. Yet it certainly would, in two ways. In the first place, dilatation of the entrance of the aorta implies a diminution in the elasticity of that vessel; and the blood after it has left the heart is urged onwards by the healthy elasticity. But again, dilatation of the mouth of the aorta commonly implies an imperfect closure of that vessel by the sigmoid valves; so that during the diastole, a part of the blood is apt to regurgitate from the aorta, and to keep the ventricle morbidly full. You see, therefore, that a deviation from the healthy state of the aorta and of the valvular apparatus which lies at its mouth, may obstruct the course of the blood, and lead to hypertrophy and dilatation, whether the deviation be in the one way or in the other; whether, I mean, the natural size of the vessel be increased or diminished. Again, disease of the mitral valve, obstructing the flow of the blood at *that* point, will lead to an accumulation in the left auricle, in the pulmonary veins, and in the lungs themselves. The auricular action is always less regular and energetic than the ventricular, so that we less frequently meet with *hypertrophy* of the auricles, but very often with dilatation. And if we go to the other side of the heart, we find hypertrophy with dilatation, and more especially dilatation of the right ventricle, when, from some reason or other, the blood passes with difficulty towards or through the *lungs*: either from disease of the pulmonary artery, or from disease in the substance of the lungs—*emphysema*, for instance; and if the difficulty be great, the accumulation and distension will affect successively the right auricle, and the *venæ cavæ*; and then we have, in most cases, general dropsy. So that, I repeat, disease in the heart tends to propagate itself in a direction contrary to that of the circulation. Furthermore, if the muscular tissue of the heart be pale, flabby, soft and weak, as it frequently is in feeble, ill-nourished, cachectic persons, or if it have undergone that kind of fatty degeneration which I formerly described, it will the more readily yield to the centrifugal pressure of the blood it embraces. In this way we may have dilatation without any hypertrophy. I am anxious that you should in the outset comprehend the mechanism by which the natural dimensions, and relative proportions of different parts of the heart may be altered in disease.

One reason why disease of the heart used formerly to be overlooked, was that these natural dimensions and relative proportions were not ascertained or much attended to. It is not easy to form any very precise estimate of the size of a healthy heart. It is commonly held that if the heart be about the same size with the closed fist of the subject, its general dimensions may be considered to be natural. Bouillaud, who has taken much pains with this matter, weighing and measuring a great number of different hearts, states that the *mean* weight of that organ, with the origin of its large vessels, and empty of blood, in adults from twenty-five to sixty years old, is from eight to nine ounces; that in subjects from sixteen to twenty-five years old it may be one or two ounces less; and that, in very large and robust persons, it may rise to ten or eleven ounces. Also, what we should expect, that the weight is less in women than in men.

So much for the general bulk of the heart. And we must have some standard whereby to estimate its relative proportions. Every one knows that the walls of the left ventricle are thicker than those of the right. Bouillaud found that the mean thickness of the walls of the left ventricle *at its base* was seven lines, while that of the right ventricle was two-and-a-half lines. And taking the thickness, generally, he says, that the thickness of the parietes of the right ventricle has not a greater ratio to that of the parietes of the left, than two to five, or even than one to three.

So again of the auricles: he lays it down that the mean thickness of the walls of the left auricle, is to the mean thickness of those of the right, as three to two.

He holds also that the mean capacity of the right ventricle exceeds, by a little, that

of the left: and that the right auricle is larger than the left. Dr. Kirkes, however, thinks that probably "the capacity of the two ventricles is exactly the same. It is difficult to determine with certainty how much this may be; but taking the mean of various estimates, it may be inferred that each ventricle is able to contain, on the average, about three ounces of blood, the whole of which is impelled into their respective arteries, at each contraction." You must always make allowance in actual cases, for the possible distension of these cavities with blood, beyond the size to which they would have contracted if they had contained no blood.

I may add, that Bouillaud declares the rule I just now mentioned, which had been proposed before his researches were instituted — the rule, viz., which makes the bulk of the healthy heart equal to the fist of the subject — to be tolerably correct. By keeping in mind these general facts, you will be better able to appreciate the appearances presented by the heart when it is taken from the body to be examined: but you will recollect that they relate to *averages* only.

Now having pointed out the modes in which the natural proportions of the heart, and of its several parts, may be morbidly altered; and given you a rough standard which may enable you to estimate these proportions in the state of health, and the deviations from them in the state of disease: I will go on to consider the symptoms, by which the altered conditions are accustomed to declare themselves. And it is with respect to the heart, as with respect to the lungs; there are *general* symptoms or signs, and there are *physical* symptoms or signs: and the information derived from these sources respectively is of variable utility. Neither of them can be safely neglected; and it is often found that the indications derived from one of these sets of symptoms are confirmed or corrected by those collected from the other. I believe it will be best to pursue the same course in both cases, and to speak, in the first place, of the signs that are brought within our notice by the sense of hearing.

But, in order that we may comprehend the *morbid sounds* of the heart, we must first make ourselves acquainted with those that belong to its healthy condition.

The heart may be heard by the ear laid flat against the præcordial region, or through a stethoscope, to beat over a certain space. That space, in ordinary circumstances, corresponds to the inferior half of the sternum, and to the cartilages of the ribs, from the fourth to the seventh on the left side. The apex of the organ may often be *seen* to pulsate between the cartilages of the fifth and sixth left ribs; about two inches below the nipple, and one inch from it towards the sternum.

This is the space over which, in the sound state of the heart and lungs, the pulsations of the former are plainly audible. But there are several diseased conditions both of the heart itself, and of the parts around it, which interfere with this rule.

In the first place, if the heart be larger than natural, it will be heard to beat over a proportionally large space. In this way it may come to be heard all over the chest in front; and behind on the left side of the spine; and even, in extreme cases, on the right side of the spine.

Again, the extent of space over which the heart may be heard to beat will be increased in proportion to the thinness of its walls; and diminished, *cæteris paribus*, according to the thickness of its walls. So that when the heart has nearly its proper size, if its walls be thin, it will be heard beyond its natural limits; and if its walls be morbidly thick, *i.e.*, if it be affected with considerable hypertrophy, it will not be heard beyond, nor even to the extent of its natural limits. I will endeavour, presently, to explain the reason of these differences.

Again, and this it is of great importance to remember, the heart may be heard far beyond its natural limits, even when it is perfectly healthy, in consequence of the lung between the ear and the heart having become solid, and therefore a better conductor of sound: and the solidification may have resulted from hepatization, or from the presence of a number of crude tubercles, or from cancerous deposits. The sound of the heart's action will also be conveyed to a distance by the liquid effusion in pleurisy, and by aneurismal tumours. If we are not aware of these circumstances, we are continually liable to fall into mistakes.

The heart is likewise heard more distinctly, and over a space which is comparatively larger, in children than in adult persons; in those who are lean and spare, than in those who are fleshy and fat; and I need scarcely say that it may be heard over a

wider extent of the chest whenever its action is augmented by exercise, by emotion of mind, or by febrile excitement.

The *impulse* of the heart is another point which you must attend to. In healthy persons who are thin, you may generally feel the stroke which the heart gives to the ribs, by placing your hand on the præcordial region. In persons who are fat, you often cannot feel the heart at all in this manner. For obvious reasons, it is felt more distinctly, over a larger space, and higher up, while the person is stooping forwards, or makes a forced expiration; less distinctly, over a smaller space, and lower down, when he makes a deep inspiration, or is lying on his back. In proportion as the heart is enlarged by disease, it can be felt more extensively: and when there is hypertrophy, the force with which it strikes the parietes of the chest is sometimes extraordinary, and very instructive. You will see the ear and head of the listener distinctly lifted at every pulsation. Sometimes the whole of the patient's body, nay his very bed, is shaken by the strong shock of the heart during its systole. There is no sign of hypertrophy so sure as that afforded by the heart's impulse. You feel, not a smart, quick, and sudden knock, but a steady, heaving, irrepressible swell, which is perfectly characteristic. You may always infer increased thickness of the walls of the organ, when you meet with this regular heaving motion; and the extent to which the whole heart is enlarged in such cases may be conjectured by the extent of space over which the heaving impulse is perceptible.

The *sounds* which we hear are two. One of them coincides, in point of time, with the impulse: and barely precedes the beat of the radial artery. It happens, therefore, when the ventricles contract; during the systole. It is called, accordingly, the *systolic* sound, or the *first* sound of the heart. The other of the two sounds coincides with the diastole, and is spoken of as the *second* or the *diastolic* sound. It takes place at the instant when the heart reverts to that place and condition in which it had been prior to the systolic movement. These two sounds occur in quick and regular succession, and then follows an interval of silence, after which the two sounds are repeated; and so on.

The two sounds are not, however, exactly alike. They differ somewhat, both in quality and in duration. The first is a dull, prolonged noise; the second a shorter and smarter sound, having more of a clacking or flapping character. Attempts have been made to assign the respective duration of each sound, and of the period of repose. I confess that I have never succeeded in measuring them satisfactorily in my mind. Probably Dr. C. J. B. Williams' estimate is as near the mark as any. He divides the whole period, from the beginning of one pulsation to the beginning of the next, into five equal parts: and allots two of these to the first sound, one to the second, and the remaining two to the interval of silence. This order of succession is called the *rhythm* of the heart, and it may be perverted.

Respecting the physical *causes* of these natural sounds there have been much recent discussion and research. Our time, however, will permit me to do little more than tell you what I believe to be the facts of the matter. And I take, first, the diastolic sound, as being the simpler of the two. It used to be ascribed to the contraction of the auricles: but that was quite a mistake. The contraction of the auricles, such as it is, happens *immediately before* each systole of the ventricles: whereas the sound in question occurs *immediately after* it, and is succeeded by the period of silence. This we know from the visible movements of the organ when exposed in a living animal. In truth, the auricular contractions are very feeble, and are not attended with any appreciable noise. I have no doubt that the second sound is produced mainly, if not altogether, by the sudden shutting of the floodgates placed at the mouths of the two great outlets of the heart. The recoiling blood forces back the semilunar valves of the aorta and of the pulmonary artery, as one unfurls an umbrella; and with an audible check as they tighten. There is no other tenable mode of accounting for the sound. Experimenters have contrived, by hooks and wires, to prevent these valves from unfolding; and then the flapping sound has been converted into a hiss. Disease of the same valves demonstrates the same things; as we shall presently see. Nevertheless, it is both possible and probable that the relapse of the whole organ to its former place may contribute an ingredient towards this second sound.

The first, or systolic sound, is more complex. Physiologists are not yet agreed as

to its cause. Upon this disputed question I cannot pretend to speak authoritatively. In all probability it is a compound sound: but it must be *chiefly* produced by the collision of the blood with the inner surfaces of the ventricles, and with the surfaces of the tricuspid and mitral valves. In part it has been attributed to the impulse of the heart against the ribs. It has been thought to consist also, in part, of the sound that results from the muscular contraction of the ventricles: that the systolic sound commences with the tightening of the walls of the ventricles, including the valves; and is prolonged by the muscular noise. You are aware, I dare say, that the vigorous contraction of a large muscle is accompanied by audible sound. If, during the stillness of night, when lying in bed, with your cheek and ear upon the pillow, you set your teeth firmly, you will hear a continuous dull rumbling, like the noise of carriage wheels in the street, and evidently caused by the action of the masseter and the temporal muscles. Dr. Williams states that, with the help of a flexible stethoscope, one may hear the voluntary jerking contraction of his own abdominal muscles: the sound being as loud as that of the heart's systole, and very like it in character. But Dr. Halford has satisfied himself, and many others who have witnessed his repeated experiments, that when the entrance of blood into the heart is prevented by forcibly compressing the venæ cavæ and the pulmonary veins, the movements of the heart go on, but the characteristic sound ceases, to recommence at once upon the re-admission of the blood. The presence of the blood in the heart during the systole seems therefore essential to the production of the sound. My own opinion is that the impulse against the ribs, and the muscular rumbling, have some share (a small share probably) in causing the sound, but that it is mainly due to the collision between the blood and the walls of the cavity which contains and moves it. Dr. Halford however declares that *all* sound ceases upon the exclusion of the blood; and he contends that both the sounds "depend upon the same cause, which is simply the backward current of the blood producing forcible closure and *tension*, first of the auriculo-ventricular (first sound), and secondly of the ventriculo-arterial valves (second sound)."

The natural sounds which I have been describing are liable to be changed, or modified, by disease. I just now told you that, *cæteris paribus*, the heart is heard more clearly and extensively when its walls are thin, less widely and loudly when they are thick. Of this Dr. Williams offers the following explanation:—"The transition of a thick muscle from slack to tight can never be so complete and sudden as that of a thin one; where there are many fibres they choke and muffle each other's vibrations; hence the sound is dull and prolonged, rather than loud and clear. If we observe the different sounds produced on tightening thin silk, and thick baize or cloth, we find that the thinness of the silk gives a unity and briefness to the impulse which it receives, and the sound is short and loud; whilst in the baize the impulse is divided and prolonged in the complexity of the fibres, and the sound is dull and less brief: so, under similar circumstances, a thin ventricle will give a louder, sharper sound than a thick one."

But other modifications of the natural sounds, of a more striking and extraordinary character, are yet to be explained. Either sound, or both, may be accompanied by a noise, which, in its commonest type, very closely resembles that produced by the blowing of a pair of bellows. Four persons out of five, I should think, if they were asked what this sound resembled, when they heard it accompanying each systolic movement of the heart, would say that it was exactly like the repeated blowing of bellows in an adjoining room. It is called, accordingly, by the French, the "*bruit de soufflet*;" and in homely English, a *bellows sound*. This is the generic sound. It may be divided into species; but it is scarcely worth while so to divide it. We are only likely to confuse our notions by over-refinement. So I will only add, that, when this bellows sound is very harsh or rough, persons will tell you that it is more like the noise of a rasp, or a file, or a saw; but all the while it is some kind of bellows sound. These sounds are often denominated *murmurs* also.

Now what is the cause of this singular deviation from the natural noises made by the successive contractions and relaxations of this hollow muscle, the heart? The whole matter may, I believe, be briefly thus expressed. The blowing sound may be occasioned by any change which alters the due proportion between the chambers of the heart, and their orifices of communication with each other, and with the blood-

vessels that respectively enter or leave them; it may also be occasioned by a preternatural velocity in the passage of the blood through a healthy and well-adjusted heart. Dr. Elliotson, I think it is, who has offered this apposite illustration of the phenomenon. If the arches of a bridge have a certain relation to the quantity of water in the river, and to the force of the current, the water passes through them quietly, and without any noise. Diminish the size of the arches, and the water begins to go through them with an audible rushing or roaring sound. The very same thing will happen if the arches remain unchanged in size, but the quantity of water in the river, and therefore its velocity and force, be augmented by heavy rains. So it is in the heart. If one of its orifices—say the aortic orifice—be narrowed, by disease of the valves, or in any other way, the blood will not, as before, glide through it smoothly and without noise, but will yield that sound which we call a bellows sound. So also, if the orifice retain its natural dimensions, but the capacity of the cavity from which the blood is driven be augmented. Nay, the same blowing sound may be produced though the cavities and orifices are all healthy, and duly proportioned to each other, if the velocity of the circulating blood be increased beyond a certain limit. If you bear this explanation in mind, it will be found applicable, I think, to almost every case in which there is a blowing sound accompanying the *systole* of the organ. If, at the same time, the valves over which the blood must pass be rigid, or rough, or even loose and vibrating, those circumstances may modify the blowing sound, and render it louder, or hoarser, than it would otherwise be, and justify the appellations of *bruit de scie*, and *bruit de râpe*, with which you will find the French books full, and many of our English books also.

But this explanation applies to a *systolic* blowing sound only. What are we to say when there is a similar sound attending the diastolic movement of the heart? Why a diastolic bellows sound will mostly, if not always, be found to result from and to denote some organic disease affecting the valves of the heart. Thus, if the mitral valve be converted, as it often is, from a pliable folding valve into a bony and rigid unvarying chink, the blood which passes through it from the auricle to the ventricle, during the diastole, may (though it seldom does) cause a rushing or blowing sound. On the other hand, the reflux of blood through the unshut mitral orifice, during the ventricular contraction, may also be attended with an audible noise; and thus we have another and not unfrequent source of a *systolic* murmur. Again, if the aortic valves are imperfect, as they often are, and do not effectually close that vessel, blood will regurgitate through them during the diastole, and produce a bellows sound. That this is the true explanation of the diastolic murmurs, I am convinced, both by the observation of disease, and by the results of experiments upon living animals. In some which were made by Dr. Hope, and which he was good enough to allow me to witness, the short clack of the diastole was at first distinctly audible; then hooks were introduced, so as to prevent the perfect closure of the sigmoid valves during the diastole, and then the short smart clack was converted into a prolonged bellows murmur; and upon letting them go again, the short smart clack recurred. The presence of a diastolic bellows sound has repeatedly enabled me to foretell some disease of the sigmoid valves, interfering with their proper function—that of forbidding the re-entry of the blood into the ventricle from the aorta; and what I have thus predicted during life, has been verified by observation after death.

Bellows sounds are occasionally caused by accidental circumstances, extraneous to the heart: by mere posture sometimes, or by distension of the abdomen, either of which may *tilt* the heart, and alter its position with respect to its great vessels. Instances are recorded of bellows sounds removed by tapping the belly in dropsy, and reproduced by the reaccumulation of the dropsical fluid. You may even make a temporary bellows sound by forcibly pressing your stethoscope upon the præcordia, especially in children, in whom the ribs are feeble and yielding. And you may fall into errors of diagnosis if you are not aware of this.

Such, then, are the principal sounds, natural and morbid, which are audible by the naked ear applied to the region of the heart, or which may be heard through the stethoscope. But we derive assistance, in respect to cardiac disease, from percussion also. It enables us to measure, in some cases, the bulk of the heart; in others, to ascertain that the pericardium is distended by fluid. In the perfectly healthy state of the viscera of the thorax, the heart is somewhat overlapped by the thin edge of the

lungs; and the sound elicited by percussion over a part of the præcordial region is intermediate between the hollow sound rendered by lung, and the flat sound yielded by the solid heart. In the centre of the præcordial region, where the heart is not covered by lung, the sound is decidedly dull. When, however, the heart is enlarged by disease, a larger part of its surface is exposed, and a larger portion of the præcordial region gives a dull sound on percussion. And when the pericardium is full of liquid, which distends and expands it, you will sometimes find that not less than a third part of the anterior and lateral portion of the left side is quite dull: and it is interesting often to measure, by percussion, the diminution or extension of the limits of the dulness, as the amount of effused fluid decreases or augments.

What I stated before, concerning the effect of different positions of the body upon the space over which the healthy beating of the heart may be heard, felt, and sometimes seen, applies, *mutatis mutandis*, to the natural dulness which the heart causes when the præcordial region is percussed. The space comprehended by this dulness is thus defined by Dr. Latham. "Take the fifth costal cartilage on the left side, and let a point, midway between its junction with the sternum, and its junction with the rib, be the centre of a circle two inches in diameter. This circle will as nearly as possible define the space of the præcordial region, which is naturally less resonant to percussion than the rest." The dulness should diminish or disappear in the supine position, and when a full breath is drawn; and increase in degree and extent upon a forced expiration, and when the posture is prone.

There is another physical sign which is much dwelt upon by Laennec, and which is sometimes very striking. In certain conditions of disease, the hand placed over the situation of the heart perceives a peculiar thrill or vibration accompanying its movements. The sensation conveyed to the hand is really very much like what Laennec compares it to, viz., that tremor which you feel, when coaxing the back of a cat while it is purring with pleasure. Accordingly he calls this sensation "*fremissement cataire*," the purring thrill. You feel this vibration often when there is present also a loud and strong bellows sound; and Dr. Thomas Davis was of opinion, that the *bruit de soufflet*, and the *fremissement cataire*, constitute, in fact, but one phenomenon, which is rendered evident to the touch by the vibrations communicated to the hand, and to the hearing by the vibrations communicated to the ear, through the solid walls of the chest. I know, however, that the *fremissement cataire* does accompany other sounds, as well as the bellows sound: sounds of which I have not yet had any occasion to speak, but which I shall make you acquainted with when we come to the subject of pericarditis. And I pass from this general account of the sounds belonging to the action of the heart, in health and in disease, to consider the other symptoms by which we judge that such disease is present.

Among the general symptoms, then, of cardiac disease, some are direct—as pain; palpitation or excessive action of the heart perceptible by the patient; irregular or intermittent action, which the patient may or may not be conscious of: and some are indirect, declaring themselves through the medium of other parts and organs—such are dyspnoea; cough; dropsical accumulations; hæmorrhages; various affections of the nervous system, especially an increased and morbid sensibility, what is usually called *nervousness*: and some others, which I will cursorily notice as we proceed.

I shall take this opportunity of considering, once for all, some of these symptoms; whether they really proceed from organic disease of the heart or not: for the determination of the question, whether they do or do not indicate such disease, is often of great moment, and is not always easy.

We are not, in general, sensible of the beating of our hearts; but when the pulsations become inordinately forcible, they make themselves felt, and the sensation is, in many cases, a most troublesome and distressing one. Palpitation implies increased force, or increased frequency—or an increase both in force and in frequency—of the contractions of the heart. Every one has experienced palpitation in his own person who has run himself out of breath. The pulsations are sometimes tumultuous also, and irregular, as well as unduly frequent and forcible; but this is by no means always or necessarily the case. There may be great palpitation with perfect regularity of the heart's action. The increased beating not only can be felt internally by the patient, but it may often be heard both by himself and by others. However, we do meet with persons whose hearts throb with excessive violence, without their being at

all aware of it. Such cases, are always, I believe, cases of disease; whereas the palpitations that annoy and harass the patient are very often connected with functional disorder only.

Irregular action of the heart consists in some derangement or discord of its rhythmical movements, and is discovered by the condition of the arterial pulse — by unnatural fluctuations in the strength, or in the number, of its beatings, or in both. Sometimes a few rapid and feeble pulsations occur at uncertain intervals, and are followed by others that are fuller and slower. Sometimes one or more beats are left out, and the next beat, as if to make up for this pause, is unusually strong. The pulse is then said to *intermit*. The intermissions may be unperceived by the patient himself; but in general they are attended with a singularly disagreeable fluttering, or trembling sensation in the breast. The pulse may intermit though the heart does not: the ventricle may now and then contract so faintly as not to propel a wave of blood so far along the artery. Intermission implies irregularity; but the action may be irregular and disorderly without intermitting.

Now, any of these deviations from the natural rhythm and action of the heart alarm people very much, and impress them with a belief that they have some fixed disease of that organ; and you will continually be appealed to for your opinion on this point. I suppose there are few medical students who have not, at some time or another, admitted into their minds the apprehension that they had disease of the heart; an apprehension engendered by its occasional palpitation or irregularity. For though there may be palpitation without irregularity, yet it is practically convenient to consider the two together.

These deviations certainly belong both to organic disease and to mere functional disorder of the heart; but I repeat, that in a great number, nay, in a great majority, of the cases in which they so distress and alarm the patient as to lead him or her to complain of them, they are unconnected with any change of structure; and this it is of much importance that you should be aware of.

Palpitation of the heart, and intermission or irregularity of the pulse, are often dependent upon some disordered condition of the stomach, and will cease at once when that disorder is rectified. It is curious that this may happen although the gastric affection does not manifest itself by any other symptom: and it is curious, too, how slight a cause may suffice to produce the irregular action. A friend of mine, a barrister, used to be very anxious about himself, because a fluttering sensation frequently occurred at his heart; an intermission of one or two beats, and then a violent throbbing when the organ again resumed its play. This is a sensation very familiar to my own consciousness, and probably most persons have occasionally experienced it. However, it happened so often to the gentleman I speak of, that it made him very unhappy. He persuaded himself that he had disease of the heart, and that he should some day suddenly drop down dead. But there was no other symptom of cardiac disease, direct or indirect, general or physical. He was accordingly told that the intermission depended upon some fault in his digestive organs; and he was advised to leave off different articles of food and drink in succession, in order to discover whether any one particular thing offended the stomach, and gave rise to the symptom. He began by abstaining from tea, which he had been in the habit of drinking in considerable quantity; and thereupon the fluttering of the heart ceased. After a while he took to tea again, and then the fluttering returned. He repeated the experiment many times, and always with the same result, till at length his mind was satisfied; and by renouncing tea altogether he got rid of his palpitation and of his apprehensions. I mention this instance, because it came within my own cognizance; but it is only a sample of many such, and *tea* is frequently found to be the disturbing substance.

I must caution you, however, against the mistake which is often made, of inferring that the heart is free from organic change because its irregular movements are accompanied by dyspeptic symptoms. Structural disease of that organ is very apt to derange the digestive functions. You will commonly find that patients who labour under such disease are exceedingly liable to flatulence of the stomach; and free eructation of the gas which plagued them mitigates wonderfully the cardiac distress. It does so, no doubt, by relieving the diaphragm from that upward pressure which had embarrassed the motions of the heart.

We judge that palpitations and irregularities are merely symptomatic consequences of gastric disorder when they occur occasionally only; when the rhythm of the heart is perfect during the intervals; and when we fail to discover any other physical or general signs that its texture has undergone alteration.

Besides these overstrong or irregular movements, which are symptomatic of disorder of the stomach, and are remedied by correcting that disorder, there are palpitations of a purely nervous kind. I mean that they depend upon a peculiar and highly sensitive condition of the nervous system; which condition is itself dependent, in general, upon a particular state of the vascular system. Persons of a "moveable" constitution, whether male or female, are subject to these palpitations: but especially young women: and, of these, such as are pale, exsanguine, hysterical, in whom the menstrual functions are deficient, or excessive, or somehow unnatural. Anæmia, if not a constant, is certainly a frequent and most remarkable feature of this nervous state. The blood is aqueous; poor in fibrine, and in red particles. The age, and frequently the sex, of the patient form leading points in the diagnosis. Nervous palpitations are apt to come on when the patient is quite at rest: palpitations that result from organic disease are, on the contrary, mitigated, usually, by repose. The occurrence of palpitations *in the night*, however, is but an equivocal circumstance, for nervous persons who dream, awake often with palpitation; and the recumbent posture is apt to excite or to aggravate the palpitations that are organic. Neither, in forming our diagnosis, can we trust implicitly to the presence or absence of physical signs. The heaving impulse of hypertrophy is indeed wanting; but, as I told you formerly, the short abrupt knock of chlorotic palpitation is often attended with a systolic bellows murmur: and this murmur is not confined to the præcordial region, but may be traced distinctly in the subclavian and carotid arteries. These unnatural sounds are common in persons whose blood has been drained of its red particles by frequent hæmorrhages, or by copious or repeated venæsection. We may suppose, in seeking to explain them, that the weak and flabby heart dilates a little, so that the healthy proportion between its ventricles and their outlets is for a time disturbed. But the sounds must in some other way also be dependent upon the thin and impoverished condition of the blood in such patients; and this reminds me of another diagnostic clue with which you should be acquainted. In nervous susceptible persons, especially if they exhibit the pallor of spontaneous anæmia, or are blanched by loss of blood, very curious noises are often audible, by means of the stethoscope, in the *neck*. Continuous rushing or roaring sounds, very like those which are to be heard in shells, and which poets feign, and the vulgar believe, to be the noise of the distant sea.

Shake one, and it awakens; then apply
Its polished lips to your attentive ear,
And it remembers its august abodes,
And murmurs as the ocean murmured there.

Sometimes the sound is more like the hum of a gnat, or the sighing of the wind through a crevice. Dr. Hope very truly states that it may be imitated, by a prolonged whispering pronunciation of the syllable *who*. Bouillaud, from its resemblance to the whizzing of a well-known toy, calls it the "*bruit de diable*." He fancied this singular sound to proceed from the arteries of the neck: but it is quite distinct from the true arterial bellows murmur, and it has been clearly shown (first by Dr. Ogier Ward), that it is produced by the descent of the attenuated blood through the great cervical veins. The sound, though continuous, has often a marked and regular increase, or swell, which keeps time with the heart's systole, and is believed to depend upon the pulsating pressure of the contiguous artery. It is best heard on the right side of the neck, just above the clavicle, and just behind the posterior edge of the sterno-mastoid muscle. You must take care not to *produce* these sounds, as you easily may, by pressure with the stethoscope. So, also, you may suspend them at your pleasure, by pressing, above the stethoscope, upon the track of the veins, so as to stop the current of blood through them, without arresting the pulsation of the arteries. This proves that the murmurs are *venous*. I have no leisure to go more into particulars concerning these sounds; but when you meet with them, concurring with cardiac palpitations, in a young, nervous, anæmic subject, the palpitations, ninety-

nine times in a hundred, will turn out to be simply functional — independent of any organic disease. No doubt there may be co-existing change of structure; but that is a rare exception, and when it does occur other signs proper to structural disease will be present, and will betray it.

Now these palpitations, and these musical or rushing sounds in the jugular veins are to be cured by remedying the state of the blood. And the remedies are preparations of steel, aloetic purgatives, animal food, the cold shower-bath, and exercise, short of producing great fatigue, in pure air.

I have further to remark, with respect to intermissions of the heart's action, and therefore of the pulse at the wrist, that they are frequently connected, both in health and in disease, with feebleness, and also with unusual slowness, of pulsation. So that a slow pulse which is likewise feeble is often converted into an intermitting pulse by depletion; by blood-letting, for example, or by an active purgative; and the intermittence may be removed again by a stimulant. I mention this now, because there is another and very different state of disease, in which the pulse is apt to intermit. I mean when there is *plethora capitis*, and cerebral mischief is present or impending. But then the pulse will be full and strong, and labouring. In these cases a stimulant treatment would of course be injurious; while blood-letting, which would *cause* the other form of intermission, is the *remedy* of this.

Some assistance in determining between organic disease and mere functional disorder of the heart may perhaps be derived from observing the position of the patient. It is stated that when there is mere nervous palpitation, the patient lies as well, and perhaps better, on the left side than otherwise: whereas, when the heart is actually diseased, the decubitus on the right side is more comfortable than that on the left. If there be any tenderness of the heart, or of its enveloping membrane, the posture on the right side is supposed to be the easiest, because the heart is further removed from the ribs, and impinges upon them during the systole with less force. However, no great stress can be laid upon this symptom.

Of the remaining general symptoms of heart disease there is not much to be said. Dyspnoea and cough are indirect symptoms declared through the lungs, between which and the heart there is a close and obvious reciprocal influence. But dyspnoea and cough are direct symptoms of pulmonary disease; and even of pulmonary disease they scarcely help the precise diagnosis. That disease of the heart may materially alter the quantity of blood that is sent to, or transmitted from the lungs, is too plain to require any formal proof; and where the quantity of blood in the lungs is affected, the quantity of air necessary to ventilate that blood must vary: in other words, dyspnoea must ensue. *Hæmoptysis* is also an equivocal symptom.

One very common effect of cardiac disease is an impeded and sluggish transmission of venous blood from the abdominal viscera. Hence congestions of various parts, and especially of the liver, which enlarges and grows tender; and the biliary secretion and functions are deranged. These symptoms are a fruitful source of mistake, leading the unwary practitioner into the belief that the whole of his patient's malady is hepatic; whom he comforts accordingly with the assurance, that "it is all liver."

The circulation through the *brain* is also apt to be much disturbed in heart diseases; and to this circumstance we must attribute the headaches and giddiness that often accompany them; the dread and causeless apprehension which such patients frequently exhibit; the cowardice and irritability which disease of the heart engenders in men who previously were intrepid, and of strong and firm nerves; also that propensity to dreaming, and especially to distressful and frightening dreams, so commonly observable in them; and the sudden startings from sleep in agitation and alarm. The relations that subsist between apoplexy and organic disease of the heart were fully discussed in a former lecture.

One of the most common indirect symptoms of cardiac disease is dropsy; yet, sometimes the disease of the heart may continue long, and even prove fatal, without giving rise to any dropsy. It will produce that symptom, or not, according as it leads to venous congestion or not. Hence dropsy is more particularly connected with dilatation and attenuation of the right cavities of the heart. But these are points to which I must revert.

Having thus run over, gentlemen, the morbid changes to which the heart, as a muscular organ, is liable; the alterations of thickness in its walls, and of capacity in

its chambers, and the derangements of the natural relations between the several chambers and their orifices; having considered, also, in a brief and cursory manner, the sounds which the heart gives out in its different movements during health, and the modifications to which these sounds are subject in disease; and having, moreover, passed in review the general symptoms which frequently display themselves in connexion with cardiac disorder, we shall be the better prepared, I hope, to investigate, when we next meet, some of the specific diseases of that important organ.

LECTURE LX.

Diseases affecting the muscular texture of the heart; and their treatment. Fatty degeneration. Rupture. Changes to which the valves of the heart are subject. Effects, and diagnosis, of those changes. Angina pectoris.

I KNOW not how I can so well put you in possession of what I know, or think, concerning particular structural diseases of the heart, as by taking them in succession, and offering a sort of running commentary upon them. The *mechanism* of those structural changes, and the altered sounds, and the other physical signs, arising out of them, I endeavoured to explain in the last lecture. Bear in mind that in this place I can do no more than draw broad outlines.

Simple hypertrophy of the left ventricle. This sometimes occurs when we can discover no mechanical obstacle to the passage of the blood out of the ventricle, which might account for it: none, I mean, by the closest scrutiny made even after death. Is it then possible that this change may be brought about by physical causes which are not permanent, and have no place within the body: such as undue action of the organ for a length of time, in consequence of habitual bodily exertion? A runner, for example, we may conceive to keep his heart beating with a degree of force and frequency beyond what is natural, for the greater part of the day; and that for many days, or weeks together. Again, can simple hypertrophy grow out of that excessive action of the heart which may be kept up, day after day, for a long period, by protracted mental emotion? It is difficult to answer these questions. But I presume that causes of this kind—that any cause, in short, which implied long-continued increase in the function of the organ,—*would* suffice to generate hypertrophy. What is certain, however, is that such causes seldom do act with sufficient intensity and constancy to produce these effects: and simple hypertrophy of the left ventricle, with no physical obstruction to the flow of blood through the heart, and no impediment to the free play of the organ, is rare.

We ascertain its existence when it does exist, first, by the account which the patient gives of himself. He has a *sensation* of beating of his heart, which he ought not to have; he feels it and hears it beating as he lies awake in bed; or even at other times when he is at rest. The pulsations are regular. Hypertrophy has no tendency in itself to cause the pulse to intermit or to become irregular. The breath may be short, but there is no marked dyspnoea: the circulation of the blood through the lungs is not much affected by this alteration of the left ventricle; they are in fact protected by the mitral valve: there is seldom any dropsy: but the arterial circulation being forced, there is a tendency to active congestion in the capillary vessels. As there is no mechanical obstacle to bridle the excessive power of the muscle, the pulse is full and strong; the face is florid; the patient is liable to headache, to bleeding from the nose, to active hæmorrhage, and to local inflammation. If you listen to the heart in such a case, you find that the systolic sound is less loud and clear than is natural. It is not heard beyond the præcordial region, nor even perhaps over its whole extent: but there is no bellows sound. And if you place your hand upon the left breast, you feel that steady, swelling, incontrollable impulsion, which I spoke of

in the last lecture, as the surest sign that I am acquainted with, of hypertrophy. Sometimes the præcordial region is manifestly bulging and prominent.

If I were to preach for an hour concerning the treatment of such cases, I could say no more than this: that they require perfect quiet of mind and body; undeviating abstinence; in short, the strict observance of the antiphlogistic regimen as formerly described; and some of the antiphlogistic remedies: particularly moderate topical bleedings, often repeated; with a close attention to the functions of the digestive organs. These are among the cases in which, if in any, we may expect to *cure* hypertrophy.

Hypertrophy provoked and sustained by inflammation of the membrane which lines the ventricle is not mere hypertrophy. That complex change is a most interesting one, and will demand our attention hereafter.

If simple hypertrophy of the left ventricle be rare, hypertrophy of the same chamber from a mechanical obstacle, or from some fixed hindrance to the easy working of the hydraulic machine, is exceedingly common. What difference, then, let us inquire, is made in the symptoms, in the treatment, and in the prospect of recovery, by the presence of a permanent physical impediment, out of which the hypertrophy has grown?

The mechanical impediment will frequently signify its existence, by causing some unnatural sound: a systolic bellows sound most commonly, which is audible over the sternum, along the course of the aorta. And the mechanical impediment will *tend* to cause faltering of the pulse; but generally the hypertrophy corrects that tendency. So, on the other hand, the mechanical obstacle corrects the tendency of the hypertrophy to cause active capillary congestion: and when the obstacle is considerable, it will prevent the pulse from being so full and strong as in the former case. If to the physical signs of hypertrophy of the left ventricle there be added a systolic bellows sound, and a disproportionate smallness and feebleness of the pulse at the wrist, we may safely conclude that there is some impediment to the escape of the blood from the left ventricle into the aorta; and that this impediment has given occasion to the hypertrophy.

Now, in this case, the hypertrophy is really an endeavour towards health. The increased power of the ventricle compensates for the bar which is opposed to the current of the blood. The blood would not be able to go on without the hypertrophy. There would ensue a tendency to stagnation in the circulation, a faltering pulse, imperfect arterialization of the blood, blue cheeks and lips, dyspnoea, dropsy; but the augmentation of bulk and force in the impelling muscle obviates this: obviates it at least for a while: puts off the evil day to a distance. Since this is the case, and since we have no means of removing the mechanical impediment, we should be mad to desire the cure of the hypertrophy, which is to a certain degree a remedy for the impediment; nor indeed could we cure it if we would. But we have to endeavour to keep it within due bounds. If the beating be troublesome to the patient, we may alleviate that symptom, and check what there may be of superfluous energy in the contractions of the morbid chamber, by abstracting blood from the præcordia by leeches; and by soliciting the action of the kidneys, by means of cooling diuretics, among which small doses of digitalis may find an appropriate place. The labouring action of the heart is sometimes calmed by the application of a belladonna plaster. In this variety, also, of the disease, it is of primary importance that no undue efforts of the body be made, and that the patient be protected, as much as possible, against all causes of mental emotion; that scrupulous temperance be enforced; and that all the functions of the body be carefully watched and regulated.

These are not cases in which we can look for recovery: but they are cases which bad management and imprudent habits may hurry on to a fatal termination: and which judicious treatment and a disciplined course of living may render tolerable, and carry forwards for a considerable period.

Under the same condition of mechanical impediment, we oftener have eccentric hypertrophy of the left ventricle: hypertrophy, *i. e.*, with dilatation. Of course the bulk of the whole heart is augmented by both of those conditions; and sometimes it becomes enormous, as big as that of a bullock. The symptoms will differ somewhat, according as the hypertrophy, or the dilatation preponderates, and therefore it will be as well to state here what are the symptoms of simply dilated ventricles. They are a

diminished *impulse* of the heart's action; and therewith a clearer sound than is natural. The first sound approximates to that of the heart's diastole; to the clacking second sound, and it is heard extensively. There is more or less tendency to fluttering palpitations and irregularities of the pulse, which is usually weak and small; to faintness and debility, and to coldness of the extremities: and when the *right* ventricle is dilated, there are some other symptoms which I shall notice presently.

Now, I say, there will be a mixture or modification of the symptoms, when the left ventricle is both dilated and hypertrophic. The dilatation will aid the mechanical impediment in giving a tendency to irregularity and intermission of the pulse; and the hypertrophy will tend to rectify that disposition. And we must *trim* our management of such cases accordingly. If the pulse flutter, we cautiously administer tonics, or stimulants: if it be steady, and the signs that belong to simple hypertrophy predominate, and are excessive and troublesome, we must starve the patient, take blood from his side, purge him and give him diuretics; but at all times keep him as *tranquil* as we can.

Simple hypertrophy of the right ventricle is not a common disease. When it occurs, it results from some actual or virtual impediment to the passage of the blood from the ventricle into the lungs. The most extreme instance of it that I ever saw, was in the heart of a medical friend's son, who died at the age of seventeen; having been for many years affected with the *morbus cæruleus* as it has been called, *i. e.*, an habitual blue state of the cheeks, lips, and tongue, finger-nails, and the skin generally; attended with shortness of breath, and augmented by every kind of exertion. It is seldom that persons thus affected live so long as this poor boy did. The heart, as is usual under such circumstances, was malformed. The septum between the ventricles was imperfect at its upper part; and the aorta belonged as much to the one ventricle as to the other. The pulmonary artery would not admit a goose-quill; the walls of the right ventricle were as thick as those of the left.

Authors tell us that hypertrophy of the right ventricle of the heart is a cause of pulmonary apoplexy. I explained to you in a former lecture why I cannot believe in this doctrine. In the first place I say that the increased thickness and strength of the walls of that chamber supply a measure of the *difficulty*, and not of the *freedom* and *force*, with which the blood is conveyed to the lungs. In the second place pulmonary apoplexy does not result from rupture of vessels by the *vis à tergo*: and is quite a different lesion from *cerebral* apoplexy. It is simply an *accident* of pulmonary *hæmorrhage*. And lastly, I never met with pulmonary apoplexy coincident with mere hypertrophy of the right ventricle. The right ventricle lies *on this side* the lungs, in the order of the circulation; and accordingly, following the rule I mentioned in the last lecture, its morbid states are for the most part *effects*, and not *causes*, of *pulmonary* disease.

The commonest affection of the right ventricle is dilatation, with or without some increase of thickness, and even sometimes with attenuation, of its muscular parietes. This is in general the consequence of *long standing* pulmonary disease; which has prevented the easy passage of the blood out of the right ventricle. And the passage of the blood may be hindered, as I showed you when we were upon the subject of pulmonary emphysema, partly, and directly, by obliteration of the blood-vessels of the lung, but mainly and indirectly by its contraction. Portions of the lung suffer primary disease, which permanently diminishes their bulk; other portions are then stretched and at length permanently dilated as the thorax expands in inspiration; and so by degrees pulmonary emphysema is produced, as a secondary disease. The same shrunken state of the lungs tends also, as Dr. William Gairdner has well explained, to constantly overload and dilate the heart; and the resistance to this tendency leads frequently to some thickening of its walls. That eminent pathologist has established the great probability "that dilatation and hypertrophy of the heart are never otherwise than secondary affections, and that they are dependent in a very great majority of cases, 1st, on valvular deformity and other obstacles to the circulation in the heart or great vessels (dilatation *from within*), and 2ndly, on the expansion of the thorax under abnormal conditions (dilatation *from without*). The consequence of either of these forms of dilatation, or even of the tendency to either of them, may be hypertrophy of the muscular substance, due to the effort of the organ to act effectively under an increased resistance to its contraction."

This condition then of pulmonary disease is often, or ultimately, attended with dilatation of the right auricle, and of the jugular veins, which stand out in relief from the sides of the neck, and exhibit an undulating sort of pulsation, produced by the regurgitation of a part of the blood, whenever the ventricle contracts. I have taken from the neck of a person dead of such disease, veins into which I could slip my forefinger. There is no surer sign of dilatation of the right cavities of the heart, and of an inadequate tricuspid valve, than abiding regurgitant fulness and pulsation of the jugular veins. With all this there is a fluttering action of the heart, an irregular pulse, great distress and shortness of breathing, a dusky skin, and blueness of the countenance, which is bloated and anxious, and a tendency to delirium and drowsiness; while, sooner or later, the whole areolar tissue of the body becomes charged with accumulated serum. Some degree of this may now and then be noticed towards the fatal close of phthisis. Much oftener it accompanies the later periods of extensive pulmonary emphysema. The same condition of the right chambers, producing the same afflictive consequences, is the very frequent sequel of organic changes which originated in the left side of the heart.

Disease, such as I am now describing, in its advanced stages especially, is difficult to treat. If you stimulate, you run the risk of increasing the patient's distress; if you deplete, you incur the hazard of producing fatal syncope, of bringing the heart to a pause from which it is never able to recover. Here, again, you must try to keep the kidneys active; you must enjoin that, as far as may be possible, all causes of agitation or hurry, everything which has previously been found prejudicial to the patient, may be sedulously warded off. I have found more benefit in these cases from steel, cautiously employed, than from any other drug. Without forcing the heart's action, it appears to have the effect of increasing the tone of its muscle; which it thus enables, *for a time*, to compete more successfully with the load it has to carry, and the impediment which it cannot overcome. We can do no more in such cases than palliate.

Hypertrophy—or dilatation—or dilatation with hypertrophy—may affect, in their various degrees and combinations, one chamber of the heart; or several at the same time: or all of them together. It would be vain to attempt to represent, in verbal description, these complicated changes. Enough, I trust, has been said, to enable you to unravel them when they come before you; and to ascertain with sufficient exactness, the general indications which they severally furnish, and the plan of treatment which they require.

You will often find the muscular substance of the heart pale, soft, and flabby; easily broken down, or penetrated, by pressure. This may occur with general debility and looseness of tissues; it sometimes accompanies a plentiful deposit of fat about the organ; and it is supposed to be sometimes also a consequence of inflammation affecting the muscle. Walls thus soft are likely to yield under pressure; but I know of no particular symptom by which we can detect with certainty the soft condition.

One mode in which such softness may originate deserves your especial attention. In an early lecture of this course when speaking on the subject of general pathology, I described two distinct kinds of *atrophy*; the first consisting in mere diminution of bulk, without change of texture; the second involving alteration of texture, without any necessary reduction of bulk. These distinctions are well exemplified in the heart. There are two forms of cardiac atrophy: one well known, in which the organ simply wastes and dwindles in all its parts and dimensions, during the course of some wasting disorder; the other newer to pathology, as yet but imperfectly understood, in which the texture of the muscle degenerates also, and suffers a sort of conversion into fat. It is not that the heart is encumbered by an excessive accumulation of adipous matter upon its exterior, concealing, dipping down among, displacing and thinning probably its muscular fibres. That morbid state of the organ is common enough. The change to which I now advert, and which has been described by Rokitanski, and illustrated by Mr. Paget, depends not upon any deposit among the fasciculi, but upon some alteration of their proper tissue. There may be no increase in the quantity of fat natural to the furrows and depressions on the outside of the heart; “the whole of the organ” (I adopt Mr. Paget's description) “may preserve its customary size, shape, and general external appearance, but it feels soft, doughy, inelastic, unresisting, and may be moulded and doubled up like a heart beginning to decompose after death. It

seems never to have been in the state of *rigor mortis*." "In colour it has not on its surface, much less on its section, the full ruddy brown of healthy heart, a colour approaching that of the strong voluntary muscle,—but it is, for the most part, of a duller, dirtier, lighter brown, in some parts gradually blending with irregular marks or blotches of a paler fawn colour."

Microscopic observation reveals the nature of these changes, and exhibits a number of minute oil-particles, scattered more or less thickly along the course of the muscular fibre. The muscle thus spoiled retains no longer its proper power, and the functions of the organ are defeated.

Of death occurring, apparently, through this fatty degeneration of the heart—a state which might easily escape the notice of any but a careful and practised examiner—Mr. Paget details three very interesting examples. They have recalled to my mind one or two instances that I have witnessed of sudden and fatal failure of the circulation, under very similar circumstances. They were perplexingly obscure at the time—but Mr. Paget's remarks elucidate what I now believe to have been their real pathology.

This insidious disorder has been studied more recently by Dr. Ormerod, the late Mr. Barlow, and others, and especially by Dr. Richard Quain, who has embodied the fruits of his own researches, and the principal facts collected on the subject by previous observers, in the 33d volume of the *Medico-Chirurgical Transactions*.

In accordance with the views which I formerly set before you, Dr. Quain distinguishes fatty growths upon the heart and between its fibres, from fatty degeneration of those fibres themselves. These unnatural conditions spring from different causes: the one being the result of an accumulation in the blood of the elements of fat; the other the result of decay and disintegration. The fatty growth may occur alone; the fatty degeneration may occur alone; but they often meet in the same heart.

In examining a heart thus diseased, the eye first notices the fainter tracing, or the utter absence, of those transverse marks which cross the fibres of all the voluntary muscles, and less distinctly those of the involuntary muscle, the heart. In an early stage of the disease, these cross lines are dimly seen, and the fibre is studded, here and there, with small dark points. When the disease is more decidedly expressed, the dots are more numerous, and the striæ disappear. These dots are little globules of oil. Lying within the sheath of the fibre, they make it soft and friable.

The parts of the heart which have undergone this change are altered in colour as well as in consistence. They are pale, like a faded leaf, or of a yellowish brown, or a muddy pink colour, and they commonly have a spotted or mottled appearance. The change of texture varies in degree, and in extent. It may render the muscle merely soft and flabby, or it may reduce it to a state in which it feels like a wet kid glove, and can be torn as readily as wet brown paper. Every chamber of the heart is liable to this kind of disease, but most of all the left ventricle, then the right ventricle, then the right auricle, and least of all the left auricle. Generally it is more evident in the columnæ carneæ, and near the endocardium, than elsewhere.

Fatty degeneration of the heart may proceed from a defect of healthy nutrition throughout the body, in consequence of some general disorder, or of natural decay in the decline of life. In such cases

FIG. 76.

Specimens of fatty degeneration of the heart.

A. Heart-fibres taken from the columnæ carneæ of the mitral valves of a young woman, æt. 30; the fatty degeneration was scarcely observable in the ventricle, where the fibres still retained their striæ.

B. An extreme case of fatty degeneration, showing an entire conversion of the muscular fibre into oil-molecules, still retaining a linear arrangement. It is taken from the right ventricle of an old gentleman, who had Bright's disease of the kidney and pulmonary phthisis, and was affected with fits during the last two years of his life.

the same morbid change is commonly manifest in other parts also; in the arteries, in the liver, in the kidneys, in the cornea.

But fatty degeneration may be limited to the heart, and even to a small portion of the heart, and then it is owing to some local failure of nutrition; of which perhaps the most common cause is a diseased condition of the coronary arteries. You are probably aware that these two vessels have no large or free communication with each other: and it is a very instructive fact that when one of them alone is diseased, that part only of the heart frequently is found to be affected which receives its supply of blood from the unsound artery. Fatty degeneration of the heart is also met with after bygone inflammation, whether of the muscular tissue itself, or of its lining or its investing membrane. It is no uncommon accompaniment of hypertrophy. In every instance the change seems ultimately traceable to deficient nutrition. To the same principle may be referred that diminution of its firmness, and deterioration of its texture, which the heart is apt to sustain in the graver cases of typhus fever.

Under this dilapidating process the walls of the heart may become so soft and yielding as to bulge out into a pouch, or even so fragile as to crack; in which latter case the patient almost always dies suddenly, the motion of the organ being stopped and strangled by the effusion of blood into the pericardium. So that to die of a broken heart, is not a mere metaphor. A clergyman from the country, whom I previously knew, called at my house in the autumn, and waited some time in my absence; but went away at last without seeing me: and after consulting Dr. James Johnson, set out for his home, ten miles on the other side of Colchester. He had been unwell for some time; had suffered occasional attacks of dyspnœa; and was unusually nervous and irritable. He must have been conscious of some severe distress, for he was extremely anxious to get home, and bribed the post-boys to drive fast. As soon as he reached his own house, he took some supper, and went to bed, apparently comfortable. Half an hour afterwards one of his servants went to him, and found him asleep. At the expiration of another half-hour, he was again visited, and was then a corpse. Among other changes, the pericardium was full of blood, which had escaped from the heart through a rent in the left ventricle, large enough to admit one's finger. That part of the ventricle which surrounded the laceration, was unnaturally thin, to the extent of a crown-piece. There are several specimens of rupture of the left ventricle in the Museum at St. Bartholomew's Hospital. George II. died of rupture of the heart. It is curious enough that a Duchess of Brunswick, of the same family with George II., died of the same disease. In her case an *ulcer* penetrated the parietes of the right ventricle, which in other respects was healthy. The death of a great and good man of our profession, and of our time, Dr. Aber-

Fig. 77.

Fig. 78.

Fig. 77.—Rupture of the heart.

Fig. 78.—Aneurism of the left ventricle, formed by dilatation of a circular portion of the anterior wall, in a girl aged 19. The pouch was filled with a laminated coagulum; its mouth was narrow, round, and smooth, and its parietes consisting apparently of endo- and pericardium, with small deposits of a soft yellowish substance between them. The disease had probably commenced 13 months before death.—St. Bartholomew's Museum. Series xii. No. 53.

rombie, of Edinburgh, was caused by rupture of the heart. In most instances, the rupture has taken place in the left ventricle.

Although this fatal accident may occasionally, as in the example just referred to, be produced by the progress of a perforating ulcer, its commonest cause is that degeneration of structure which we are now considering. There is reason, indeed, to believe that it is very rarely owing to any other cause. Among 83 fatal cases of fatty degeneration of the heart, collected by Dr. Quain, there were 28, or about one in every three, in which laceration of its muscular tissue was discovered after death. In eighteen of these, the outer wall of the left ventricle was ruptured; in three, that of the right ventricle; in one, that of the right auricle; in one, the septum between the ventricles. The rent in a few other of these cases had not gone through the muscle.

The left ventricle is also liable, almost exclusively I believe, to those partial distensions of its walls into lateral cells or pouches, which are spoken of as aneurisms of the heart.

Is there any sign, or any group or succession of symptoms, by the notice of which we can assure ourselves that a living patient's heart is affected with fatty degeneration? I know of no such signs. When that change depends upon a local cause, and is limited to the heart, it is always associated with other changes, of an earlier date; and its proper symptoms, if it have any, are then mixed up and confounded with those of the earlier structural disease. When it proceeds from some general cause, we may sometimes infer its presence with more or less of probability.

There are no auscultatory signs peculiar to the movements of a fatty heart. The pulse has been observed to be weak, sometimes irregular, sometimes remarkably slow; but these qualities are frequent accompaniments of other morbid conditions. The same is to be said of shortness of breath; of attacks of syncope, which are common; of coma, and of præcordial pain, which have been less often noticed in these cases. In seeking to form a diagnosis, the time of life must be taken into account. The fatty degeneration, when it is the result of general decay, is prone to begin about what has been called the climacteric period — the sixty-third year. In more than one half of Dr. Quain's cases, the age of the patients was above sixty. In twenty-one instances out of sixty-eight, death took place in the way of *syncope*. Of the whole number (eighty-three), sixty-eight died *suddenly*. Death is apt to occur upon some shock, or unusual effort: — a hasty ascent, straining at the water-closet, the act of vomiting. "The principal character (writes Mr. Paget) which all these cases seem to present is, that they who labour under this disease are fit enough for all the ordinary events of calm and quiet life, but are wholly unable to resist the storm of a sickness, an accident, or an operation." I believe this to be generally true. Dr. Begbie has, however, recorded two interesting instances of this malady, by which the lives of two eminent men were cut short (Dr. Chalmers and Dr. Abercrombie), both of whom "were actively engaged up to the hour of death in the labours of two most arduous and onerous professions."

I say that the evidence of fatty degeneration of the heart can never amount to more than presumptive evidence. But if there be tokens of feebleness of the heart, yet no tokens of any valvular or mechanical flaw — if the patient have attained his "grand climacteric" — if he have shown of late a tendency to grow somewhat fatter, and somewhat paler also, and sicklier in complexion — and if there be withal a marked *areus senilis* — then you may reasonably conjecture that (to use Dr. Begbie's words) "the great organ of life is yielding, through the progress of time, to those organic changes which mark the decay of its structure, and foretell the not distant cessation of its long-continued functions."

The last circumstance that I have mentioned, the presence of the *areus senilis*, furnishes a strong presumption that the fatty change may be in progress elsewhere also in the body. But you must not give this symptom more weight than it deserves. The cornea is sometimes alone in suffering the change. I am acquainted with a gentleman under forty years of age, who, enjoying excellent health, presents a well-pronounced *areus* in both his eyes, especially at the summit and at the base of the circle, and in whom that appearance has remained unaltered, certainly since he was twenty-four years old, and perhaps from an earlier date.

When rupture ends the scene, usually there is sharp pain at the time of its occur-

rence, and the final struggle is soon over. It would appear, however, from two cases related by Dr. Latham, that laceration of the *septum*, though marked by severe and abiding pain, is not necessarily fatal within so brief a period. One of these patients was kept alive by stimulants for three days after the presumed instant of the rupture. The other endured eighteen hours of mortal agony; and, judging from the symptoms, it seems not improbable that the rupture took place nearly three days before he died.

For that fatty ruin of which I have been speaking there can be no repair. Yet much may be done, even by drugs, for our patient's comfort; and more, by counsel and warning, for his safety. That portion of the muscle which still preserves its primitive structure and qualities may be sustained in its imperfect functions by medicines calculated to renovate the blood, and so to strengthen the muscular tissues. Great improvement does often become manifest under the cautious employment of preparations of iron. When syncope is threatened, diffusible stimuli may be freely used. Above all, you must inculcate temperate habits, and a life of constant quiet. The patient must never be tempted nor surprised into any act which implies unusual effort. He must, for instance, lose a journey rather than hurry on foot to a railway train for which he is late. He must be content to get wet through, rather than run for shelter in a sudden shower. He must never lift a burden, nor climb stairs hastily, nor strain to relieve costive bowels. Neither will it be safe for him, even on what seem legitimate occasions, to yield to feelings of anger, or any kind of excitement. These cautions are indeed more or less applicable to all cardiac disorders; but they are especially requisite whenever there is reason to suspect that the texture of the heart is infirm, and incapable of bearing the stretching pressure of a hurried, or of an impeded, stream of blood.

Many of the morbid conditions of the muscular substance of the heart spring from pre-existing morbid conditions of the membrane which lines, or of the membrane which invests, the heart. It is necessary therefore, in the next place, to inquire into the nature and history of these morbid changes: and I will first request your attention to the diseases of the lining membrane. The investing membrane is familiar to you as the *pericardium*. Of late years, since the diseased states of the internal membrane have been more studied and understood than they formerly were, it has been called the *endocardium*: a convenient enough name, which may occasionally spare us circumlocution. Now this endocardium is liable, among other changes, to inflammation, under which it becomes whitish, opaque, and covered sometimes with a thin layer of coagulable lymph. In a well written and well reasoned essay, which you may see in the *Lancet* for 1846, Dr. Munk has shown how hypertrophy of a chamber of the heart may be engendered by chronic or subacute inflammation of its lining membrane; and, what is most interesting, how such hypertrophy may be cured, when the disease is detected and treated in time, by means which arrest and remove the endocarditis. General diffused inflammation, or other change, of the membrane is, however, comparatively rare. Certain parts of it are much more obnoxious to disease than others: those parts which enter into the fabric of the valves and orifices of the organ. The membrane is here in close contact with a dense fibrous tissue; and participates in the changes to which that tissue is subject. And it is an important fact, that the membrane, valves, and orifices of the left side of the heart, as well as its muscular substance, are much more frequently affected with disease than those of the right side. I have adverted to this fact before. What is the prevailing cause of it I cannot tell; but it seems to be a portion of a more general fact; namely, that the arterics are more liable to chronic morbid changes than the veins. Some explain the difference by alleging that the left side of the heart has the heavier task to accomplish. But nature seldom executes her purposes so clumsily, as not to adjust the strength of her machinery to the labour it is destined to perform. Others remark that fibrous tissue is more abundant, and therefore the changes proper to that tissue are more numerous and extensive, on the left side. And this may be the true explanation. Others, again, have conjectured that the arterial blood is more irritating than the venous. But there is no evidence of this: and it is better to content ourselves with noticing the fact, without attempting to account for it by mere gratuitous hypothesis.

You are not, however, to suppose that the right heart is exempt from valvular disease. When there is much change in the left, we often find a less degree of the same

kind of change in the right. The valves of the pulmonary artery are, perhaps, the least frequently of all the valves found otherwise than healthy.

Many of the alterations that take place in the internal lining of the heart result, apparently, from inflammation, which causes a deposit of lymph upon or beneath the serous membrane. The valves are apt to lose their thinness, their transparency, and their pliancy. They become thick, stiff, puckered, curled up, or glued to each other, or to the opposite walls of the channel. On the other hand, quite independently of inflammation, they may become morbidly thin, riddled with holes, and even rent asunder. What are called vegetations or excreescences may also project from them, very much resembling warts. Or they may be converted wholly or partly into bone.

FIG. 79.

Fig. 79.—Fibroid thickening of the mitral valve.

FIG. 80.

Fig. 80.—Fibroid thickening of a pulmonary valve, extending symmetrically on both sides of the curtain, and consisting of a soft fibrillar deposit. It was found in a man who had a broken spine.

Alterations of some kind or another are very frequent in the *semilunar valves* of the *aorta*. When they are of such a nature as to diminish the orifice during the systole, they commonly occasion a systolic bellows sound. When the diseased valves offer no obstruction to the exit of blood from the ventricle, but do not close again immediately afterwards, so as effectually to prevent the reflux of that fluid from the aorta, they commonly give rise to a diastolic bellows sound. When both these defects of function occur, there is often a *double* bellows sound; a sawing alternate noise; one murmur during the systole, another, distinguishable in tone and quality, as well as in time, during the diastole. These sounds are conveyed along the tube in which they are formed, and are therefore most audible in the track of the aorta, as it leaves the heart. If the sound be diastolic, it will *take the place* of the smart clack of the second sound of the heart, or perhaps prolong it. Sometimes the new sound is very loud and eurious. I had a patient in the hospital last year, in whom this diastolic sound was, in character and intensity, like the cooing of a pigeon. The patient could plainly hear it: nay, it could be heard by a person standing near him, but not touching his body, even with a stethoscope. In that instance we found one of the aortic valves irregularly thickened, with its free edge loose and flapping, and

FIG. 81.

Ossification of the mitral valves. From a preparation in Dr. Gross' cabinet.

unable to fulfil its function of closing the aperture. During the diastole it was retroverted, and vibrated in the regurgitating stream of blood; and thus, no doubt, the musical note, heard alternately with the first sound, was produced. In March, 1837, I heard in a man (Henry Milton) who was under Dr. Latham's care in St. Bartholomew's Hospital, and who had acute rheumatism, a very shrill diastolic sound, like the repeated whining of an imprisoned puppy-dog wishing to be released. This remarkable sound was audible, by means of the stethoscope, even in the radial artery. The patient died at last in St. George's Hospital, and his case is mentioned in Dr. Hope's book on the Heart. One of the aortic valves was torn downwards to some distance from its edge, and formed a flap which was perforated by a round hole.

FIG. 82.

FIG. 83.

Fig. 82.—Aortic valves of a child aged four years; they are opaque and thickened, and their free margin curled backward towards the artery. Two of the valves are closely united by their adjacent margins.—St. Bartholomew's Museum. 11th Series, 52.

Fig. 83.—Atheromatous deposit in the valves of the aorta of a man aged 26, with rupture at the point marked by *; there was also congenital union at the point (marked by †) of two of the valves. The case is described in the Reports of the Pathological Society, vol. iv. p. 100.

I need not again point out to you the manner in which such disease of these semilunar valves tends to produce hypertrophy and dilatation of the left ventricle.

FIG. 84.

FIG. 85.

Fig. 84.—Aortic valves of a man æt. 47, rendered perfectly rigid by calcareous deposit. The patient was affected with granular kidneys and cirrhosis of the liver.

Fig. 85.—Ossification of the aortic valves; a thick calcareous deposit has taken place between the valvular membranes, interposing a rigid and almost imperforate diaphragm between the cavity of the heart and the vessel. A. Upper surface. B. Under surface.—From St. George's Hospital Museum, E 18.

The *mitral* valve is often thickened; and it is particularly subject, more so even than the aortic valves, to ossification. And the effects of the ossification are to prevent its closing the auricular orifice during the systole; and to prevent its lying flat against the walls of the ventricle, and allowing a free passage of the blood out of the left auricle, during the diastole. The orifice is often converted into an unvarying oval slit, having puckered edges, and resembling a button-hole; or the valve projects, like a thimble of bone, into the left ventricle. And it is remarkable how small the chink,

which is thus permanent, may be, and yet life go on. The heart having been taken out of the body, and the auricle filled with water, I have seen the water pass into the ventricle, by its gravity, *stillatim*; drop by drop.

Let me just remind you, that the direct and necessary consequence of constriction of the mitral orifice, is an accumulation of blood *behind* it; *i. e.* in the left auricle, in the pulmonary veins, in the lungs. Hence so much mechanical congestion, that the blood bursts at length through the bronchial membrane; hæmorrhage, slow or copious, ensues from the air-passages; and *pulmonary apoplexy* is formed.

In extreme cases, where the mischief is chiefly confined to the mitral valve, the blood necessarily reaches the ventricle in a penurious manner; that chamber contracts unsteadily and irregularly; and its cavity sometimes diminishes. This I think I have seen. But far more commonly there is disease of the aortic valves also; and the condition of the left ventricle is that of hypertrophy with dilatation.

When there is a permanent chink in place of the limber valve, there may be a double bruit. The first heard during the systole, and produced by the regurgitation of blood from the ventricle into the auricle, through the rigid slit. This is common. The second accompanying the diastole, and resulting from the mechanical impediment to the free passage of the blood from the auricle into the ventricle. This is uncommon. The constriction must be great for the diastolic murmur to occur at all: and when it does occur, it is faint; from the comparative feebleness (I presume) of the auricular contractions.

The form and the consistence of the altered valves being the same, no difference whatever in the sounds, or in the general symptoms, will arise from the particular nature of the changes. It will, I mean, make no difference whether the obstacle to the flowing blood, or the imperfect closure of the orifice, depends upon mere thickening of the valve by cartilaginous deposits, or upon ossification, or upon wart-like vegetations. These last may be found upon any of the valves, but like other morbid states they are less frequent on the right than on the left side of the heart; and they are most common of all on the aortic valves. Ossification — the accumulation of the phosphate of lime — is almost confined, I believe, to the left side. I never saw the tricuspid valve, or the semilunar valves of the pulmonary artery, converted into bone.

The warts, or wart-like excrescences, which are so often found upon the valves of the heart, are very curious things. Sometimes they are separate, and in rows like beads. Sometimes several appear to spring from a common base, which spreads out so as to exhibit a cauliflower appearance. And occasionally they hang in long strings from the valve into the adjoining chamber of the heart. In a patient of Dr. Hawkins', I saw a cylindrical excrescence of this kind which measured an inch in length. The valves presented slit-like perforations; and from the edge of one of these slits in the mitral valve, this long vegetation dangled into the ventricle. The whole of the valves of the aorta were covered, on their ventricular surface, with similar but shorter excrescences.

They vary much, these vegetations, in consistence. Sometimes they are soft, easily crushed, and capable of being readily detached from the smooth surface of the valve. Others are more firm, and yet separable from the valve without injury to it. Others, again, are so adherent, so rooted into the valves, that they can be removed only by tearing or cutting them off. They are found sometimes on the free edge of the valves; sometimes on their surface, or even on the inner membrane of one of the chambers, especially of the left auricle.

Much difference of opinion has prevailed respecting the nature and origin of these singular appearances. It was a common notion among the French, at one time, that they were really, what they so much resemble, venereal warts. What seems to be certain is, that they are somehow connected with *inflammation* of the internal lining of the heart; and of that which covers the valves in particular. But, then, are they lymph poured out from the inflamed membrane? or are they fibrin deposited from the blood upon an inflamed membrane? It is probable that the last is, sometimes at least, the true explanation of their origin. You know, that when the membrane lining a vein becomes inflamed, the blood in contact with it has a strong tendency to coagulate upon it, and to adhere to it. The fleshy excrescences found on the valves are often attached to the edges of slits in the valve: the broken surface having pro-

bably been the especial seat of inflammation. When the formation of vegetation is recent, they are very soft and frangible. But the most interesting fact that I am acquainted with, in evidence of the mode in which these little projections may arise, is one that accidentally came to light in one of Dr. Hope's experiments upon an ass, at which I was present. The aortic valves had been held back by a wire passed into the vessel, with the view of ascertaining the physical cause of the second sound. The animal had previously been rendered insensible by a narcotic poison; and the circulation was kept up—languidly, however, towards the last, by artificial respiration. Upon the final cessation of the heart's motions, the organ was removed from the body and examined: and the valve that had been mechanically irritated by the wire was found studded with these little wart-like appearances, which were so soft as to admit of being readily brushed off from the subjacent membrane. Here the deposit took place after the death of the animal, and while some of the functions of organic life alone were kept up by the artificial breathing.

Some curious circumstances still remain to be mentioned, which, in some instances, are connected with the formation of these warty vegetations. I shall not, however, enter upon them in the present lecture: but when I speak, at our next meeting, of rheumatic inflammation of the heart and its membranes.

Any or all of the lesions that I have been describing may and must lead, at length, according to their places and magnitude, to some of those changes in the actual and relative dimensions of the heart that were considered in the last lecture. They obstruct the stream of blood when moving in its natural course, and when its passage out to be free; or they allow of its *refluent* course, when that ought to be effectually opposed: and the necessary results, in either case, are dilatation of one or more of the chambers of the heart, with thickening, or with attenuation, as the case may be, of its walls. I have already spoken of the symptoms, physical and general, to which these secondary changes give rise; and of the treatment which they admit and require.

There being valvular disease, and that valvular disease giving rise to a bellows-sound, can we distinguish the particular valve affected? Generally, we can. Our skill in diagnosis outruns here, as indeed it too often does, our skill to cure. A few simple rules and considerations enable us, in most cases, to satisfy our natural curiosity to penetrate the exact condition even of changes that are incapable of repair. These rules relate chiefly to the time when the murmur is heard; to the direction in which it is most audible; and to the state of the arterial pulse.

When a bellows-sound accompanies the systole, it must be caused by a current passing *out* of a ventricle. But serious disease of the valves, sufficient to occasion a murmur, on the right side of the heart, is very rare. In nineteen cases out of twenty, valvular murmurs belong to the left side; so that practically the distinction lies, almost always, between two orifices, the mitral and the aortic, the inlet and outlet of the left ventricle. The natural inlet has become an outlet also: or the natural outlet is obstructed. Now if the sound be heard at the base of the heart, and along the track of the thoracic aorta, up towards the right clavicle, and even in the carotids; and if it be less audible towards the apex, and if the pulse be steady and regular, the mischief is seated in the semilunar *valves of the aorta*: there is some obstacle which produces a ripple in the onward stream of the blood.

On the other hand, if the pulse be irregular, and if the sound be better heard down towards the apex of the organ, on the left, it is owing to regurgitation through a diseased *mitral* valve. Such regurgitation is often attended with a purring thrill.

When, what scarcely ever happens, the sound does result from injury of the semilunar valves of the pulmonary artery, it is heard plainest in the track of that vessel, up towards the *left* clavicle. So, also, a murmur produced by change in the tricuspid valve would be loudest towards the apex, on the right. The arterial pulse for obvious reasons is but little influenced by disease affecting the orifices of the right heart.

Again, if the morbid sound be diastolic, it accompanies the entrance of blood *into* a ventricle; and for similar reasons to those assigned before, the fault is most probably in the *left* ventricle. It may be owing to the direct but impeded passage of the blood from the left auricle through a narrowed mitral orifice: yet this *very* seldom occasions any audible noise. Or the diastolic murmur may proceed from regurgita-

tion through the defective aortic valves; the natural outlet having become an inlet also; and this is exceedingly common. We attend, as before, to the situation and the track in which the sound is the loudest. We listen also for the smart clack of the natural second sound; and if it be not audible or be very indistinct, we have, in that circumstance, corroborative evidence of an imperfect aortic flood-gate. Moreover, we are again assisted by the pulse. The pulse of aortic regurgitation is, sometimes at least, very striking and peculiar: sudden, like the blow of a hammer, without any prolonged swell of the artery. This pulse always reminds me of the well-known chemical toy, formed by including a small quantity of liquid in a glass tube, exhausted of air, and hermetically sealed. On reversing the tube, the liquid falls from one end of it to the other with a hard short knock, as if it were a mass of lead. The sensation given to the finger by the pulse, when there is much regurgitation through the aortic valves, is very similar to this. It is as if successive balls of blood were suddenly shot along under the finger. Dr. Hope calls this pulse a *jerking* pulse; the pulse of unfilled arteries. And this abrupt pulse makes itself *visible* in the arteries; the wave of blood lifts, and moves, and sometimes contorts the vessel. When this kind of pulse occurs with a diastolic bellows-sound heard along the track of the aorta, and the short clack of the second sound is absent or muffled, you may be quite sure that the aortic orifice is patulous during the diastole. The reflux of the blood, when the patency is great, is strong enough sometimes to produce a palpable shock or jog, called the diastolic impulse. And this refilling of the ventricle from the artery may even provoke it to a supernumerary contraction.

In a patient by whom I was lately consulted, the hard, sudden, hammering pulse led me to conclude that the blood regurgitated from his aorta: and accordingly, upon applying my ear to his chest, I discovered a loud murmur, coincident with the diastole, and most distinct in the direction of the right clavicle. The shock of this man's artery was plainly to be felt through his clothes, by one's hand laid lightly upon the bend of his arm. His wife told me that, for five years past, this jarring blow had made it uncomfortable for her to take his arm when they were walking together. The same kind of jerking impulse was strikingly perceptible in the femoral arteries, and in the carotids.

Of regurgitant sounds belonging to the right side of the heart I can tell you nothing. I never heard one, that I know of, from the pulmonic valves. Through the tricuspid orifice the blood is believed to be often reflux; causing, as I stated before, turgescence and pulsation of the jugular veins. The structure of the valve permits this ebbing movement of the blood under circumstances which might otherwise be perilous. The tricuspid has accordingly been called the *safety* valve of the heart. But the reflux seldom, if ever, announces itself by a bellows-sound.

We cannot always thus rigidly connect morbid changes with definite signs. Disorders arise of which the symptoms are more cognizable and constant than the nature or exact seat. We assign a name to the peculiar assemblage of symptoms, and make it thenceforth a distinct object of our study; tracing the symptoms as well as we can up to their organic causes and conditions. Now the complaint called *angina pectoris* is one of this kind. It is, moreover, a very curious and a fearfully interesting disorder; and I shall devote the remainder of the present hour to its consideration.

This disease was first accurately described, in this country at least, by the celebrated Dr. Heberden, the author of the Commentaries. It had been adverted to by many writers before, but obscurely; and Dr. Heberden's observations were quite original. The description that he has given of the complaint, in the second volume of the Transactions of the College of Physicians, is very accurate and striking. He calls it a *disorder of the breast*; and observes that "the seat of it, and the sense of strangling and anxiety with which it is attended, may make it not improperly be called *angina pectoris*."

"Those who are afflicted with it are seized whilst they are walking, and more particularly when they walk soon after eating, with a painful and most disagreeable sensation in the breast, which seems as if it would take their life away if it were to increase or to continue. The moment they stand still all this uneasiness vanishes. In all other respects the patients are, at the beginning of this disorder, perfectly well; and in particular have no shortness of breath, from which it is totally different."

Such is the brief description of the malady given by Dr. Heberden. You will observe, that the distress occurs in paroxysms; and the patient, at first, has intervals of apparent health: and even when the disease is more advanced, he has periods of comparative ease between fits of suffering. The paroxysms are especially liable to come on when the patient is walking, and, above all, when he is ascending, — going up a hill. He is then seized, all at once, with a very painful sensation, which seems to be, in many cases, indescribable, but which is always referred to the heart, or its neighbourhood. Sometimes the sensation is spoken of as being a spasm, as giving the sufferer a notion of constriction. I have been told by one who laboured under this disorder, that he felt, during the paroxysm, as if the sides of his chest were held together by a transverse bar of iron. The impression is constant that to continue the exertion which has produced the attack — to stir another step — would be fatal. Yet the patient is not out of breath. It is not dyspnoea that oppresses him; for he can, and generally does, breathe freely and easily. He lays hold of any neighbouring object for support. His face is pale and haggard; and you would suppose, from his appearance, that he was actually at the point of death. But in the early stages of the disease, the pang soon subsides, the distress is over, and the patient is entirely himself again. It is a singular fact, which I cannot at all explain, but of which I have been assured by several persons affected with this disorder, that when the pain and inability to stir a step further have come on after a short walk, and have subsided upon the patient's stopping, he has often been able to resume his walk, and to pursue it for a long while, without any repetition of the distress.

After the lapse of some time, perhaps of some months, the anguish does not so instantaneously cease upon standing still; nor does it always require some bodily exertion to bring it on. It will occur when the patient is quiet, even in bed. He feels as if the action of the heart were arrested; and he is obliged to rise up, every night it may be, for many weeks together. In exquisite cases it will be brought on by causes of any kind that slightly accelerate the circulation: coughing, straining at stool, mental emotion.

The pain, which is at first referred to the left mammary region, shoots backwards often, towards the spine, or across the chest below the clavicles. Frequently it extends, accompanied by a sort of numbness, to the left shoulder, and down the left arm; stopping short, in a curious manner, and from some inexplicable cause, either just about the insertion of the deltoid muscle, or at the elbow, or at the wrist. Sometimes, however, it runs down to the very extremities of the fingers; particularly of the last two fingers, following mainly the course of the ulnar nerve. Occasionally similar pains affect the right side and arm; and now and then, all the four extremities at once. There is (I say) no dyspnoea in the genuine form of the disease; although you will find it stated by some modern writers, of good repute, that the paroxysm is accompanied with difficulty of breathing. In the instances that I have seen, and they have not been very many, the patient was able slowly and fully to inspire and expire, even when the fit was on him. The truth I believe to be, that other affections, more akin to asthma, have been confounded with angina pectoris; and this confusion has led to the belief, that it is not altogether so dangerous a complaint as used to be thought: but in its genuine shape it is undoubtedly a very fatal disorder. Sir John Forbes, by a diligent search among authors, has collected some statistical facts respecting it, which are worth remembering. Thus, out of eighty-eight cases, eight cases, or one in eleven, occurred in females. The ages in eighty-four of these eighty-eight cases are recorded; and of the eighty-four, seventy-two were above fifty years; and twelve, or one-seventh of the whole, under fifty years. It is a disease, therefore, for the most part, of advanced life: and this alone would afford a strong presumption of its dependence upon some organic change. Again, the event of the disease was recorded in respect to sixty-four of the patients. Of these forty-nine died, almost all of them suddenly; while fifteen recovered or were relieved. And among the forty-nine fatal cases, there were only two of women.

That the seat of the disorder is the heart, or the aorta, and that it consists in some structural change, can scarcely be doubted. Yet some pathologists are disposed to consider it a merely neuralgic affection, "commencing, for the most part, in the pneumogastric nerve, and spreading in different directions, as other nerves become involved." But this doctrine is scarcely consistent, in my judgment, with the facts —

First, that the paroxysm is excited by such causes as are "especially calculated to disturb the natural action of the heart, bodily exertion, and mental emotion;" and, secondly, that the disease is so very frequently and so suddenly *fatal*. This is not all the character of mere neuralgic diseases in general. And when we add to these facts the further fact, viz. that, in a vast majority of instances, organic disease of the heart, or of the great blood-vessels, has been discovered after death, I think we shall be obliged to admit, that the symptoms are often (I believe I might say always) dependent upon cardiac disease. One theory explains the "breast pang," by supposing that the blood, whenever its movement is accelerated by exercise or otherwise, arrives in the heart faster than it can be transmitted onwards; and accumulating in its cavities, painfully distends them. I confess that this commends itself to my mind as being a very reasonable theory. The great Dr. Jenner took a most ingenious view of the matter, which was made public and further enforced by Dr. Parry. He had found, in examining the bodies of some who had died of well marked angina pectoris, that the coronary arteries of the heart were ossified; converted into bony canals, and constricted in their calibre. He thence concluded that the paroxysms result from the circumstance, that when some increase of the muscular contraction of the heart happens to be called for, the increased supply of blood, rendered necessary by the additional exertion, is not capable of being furnished by the diseased nutrient arteries of the organ; that the heart comes to a stand, because its muscular-tissue is not duly injected with arterial blood. The patient is on the very brink of fainting; nay, does at length faint irrevocably. He accordingly called the disease "*syncope anginosa*." And this simple and beautiful theory was for some time admitted as the true one. However, later investigations have abundantly shown that angina pectoris may occur in a decided form, without there being any ossification or other disease of the arteries; and, on the other hand, that the coronary arteries may be ossified, and yet no angina pectoris be the result. Moreover, Dr. Jenner's theory does not account satisfactorily for the *pain*.

I may here again avail myself of the researches of Sir John Forbes, and give you a numerical account of the organic changes in the heart that have been found associated with this disease. The total number of instances collected by him, in which the body was examined after death, was forty-five. Of this number there was disease found in the liver only, in two instances: organic disease of the heart, or great vessels, in forty-three. Sir John Forbes, indeed, makes the last number thirty-nine, instead of forty-three, excluding four cases in which nothing morbid was found in or about the heart, except an excessive coating of fat. This Dr. Fothergill considered the essence of the disease: and certainly a heart cannot be said to be in a healthy condition which is thus loaded with adipous matter. The fat is generally deposited at the expense of the muscular substance, which is apt in such cases to be thin, pale, and soft; atrophied, in short. Taking, however, the table as it is given by Sir John Forbes, the thirty-nine cases, in which there was no disease except in the heart and great vessels, were thus distributed:—In ten of the cases there was organic disease in the heart alone; in three, organic disease of the aorta alone. In one instance only was the disease confined to the coronary arteries; but there was ossification, or cartilaginous thickening, of the coronary arteries, combined with other disease, in sixteen instances. Again, there was ossification, or other disease of the *valves* of the heart, in sixteen cases also. There was disease of the aorta (ossification, or dilatation, or both), in twenty-four cases; and in twelve cases there was preternatural *softness* of the heart.

Now I strongly suspect that this last condition, preternatural softness—in other words, fatty degeneration—will ultimately prove to be the main physical condition of angina pectoris. To express what I mean somewhat differently:—that group of symptoms to which we give the name of angina pectoris, is (as I conjecture) an authentic exponent of that physical state of the heart to which we give the name of fatty degeneration. When the examples collected by Sir John Forbes were recorded, this morbid change was unrecognised by medical science, and the diminished consistence which it implies would easily escape notice. Observe that the two things do often assuredly go together. Several of Dr. Quain's instances of fatty disease, were also instances of true angina. Disease of the coronary arteries is perhaps the most frequent source of partial fatty degeneration. Disease of the coronary arteries is

perhaps the most frequent accompaniment of angina pectoris. The substantial change, and the nominal disorder, both belong to the same advanced period of life; both are prone to end in sudden death, and in sudden death of the same kind, death by syncope. As exacter observations multiply, I expect that angina pectoris will be acknowledged as the surest, as the only sure, indication of a fatty heart.

Pain of a peculiar character; a feeling of immediate dissolution, terminated often by actual syncope: these are the prominent and principal elements of angina pectoris. If these depend on fatty degeneration, it is supposable that one or more of them may be wanting. Dr. Quain teaches us that the inexpressible sense of dying is sometimes the only symptom of the disease which he is portraying. Sometimes the pain is added; frequently the syncope. And this is intelligible if (what I think probable) the anguish results from over-distension of the unsound heart. Syncope may occur without such distension. The softened state of the muscular tissue would admit of its being stretched a little whenever the centrifugal reaction of the contained blood was augmented; augmented by posture, by bodily effort, or by mental agitation. And this facility of yielding under a less and less degree of disturbing pressure would accord with the ascertained fact that fatty degeneration is a progressive change. The cardiac nerves may be variously implicated in the textural alteration, and may variously resent the distending force. That slight over-expansion of a heart so diseased should excite the breast-pang is conceivable enough. We are familiar with pain of a similar sharp kind when the intense is stretched by pent-up gas in colics. The *juvantia* of the disorder favour the same view. Stimulants, helping the languid and labouring muscle to contract effectually upon its contents, are effectually also, often, in relieving the paroxysm. This appears to me a more probable theory of the phenomena of angina pectoris than the theory which ascribes them to mere neuralgia, or the theory which ascribes them to spasm of the heart. Yet both these theories have been speciously advocated. To that which I offer you, you may give as much weight as it may seem to deserve.

I have spoken of this disorder as continuing to recur for months; it may even be for years: but it is frequently fatal within a much shorter period. Nay, the time between its first manifestation and its mortal close is, not very seldom, appallingly brief. My friend, Dr. Latham, lately gave me the following sketch of a case of this kind, which had fallen under his own observation. A gentleman, about fifty years old, was recovering from the influenza, of which nothing remained but a slight cough, that troubled him at night. It was to relieve this that Dr. Latham was consulted. The gentleman looked perfectly well. After Dr. Latham had prescribed for this little ailment, the patient begged to see him the next day to talk over with him (he said) a very strange affection he had. Accordingly he then described a paroxysm of angina pectoris in terms that could not be mistaken; dwelling especially upon the præcordial pain, the sensation down the left arm, the feeling of approaching dissolution, and then the perfect recovery. This gentleman had, during the previous summer, performed a walking tour through Switzerland, and returned home in excellent health. The first notice of his angina was less than a month ago, when he was walking up Hampstead Hill. It was then that he had his first paroxysm. In the short period which had elapsed, the attacks had rapidly increased in severity and frequency: occurring now every two or three days, or every day, or several times a day, with or without an obvious exciting cause. Dr. Latham made a careful examination of the chest, and found the respiration perfect, the heart free from all unnatural murmurs, and its beats rhythmical. The only thing that particularly attracted his notice was the exceeding feebleness of its impulse. In the afternoon of the next day Dr. Latham visited him again, when he described a paroxysm he had suffered in the course of the morning, of much greater severity than any that he had hitherto experienced. Dr. Latham saw enough to convince him that his patient's existence was very precarious: and as he had previously been a stranger to him, he inquired about his friends, and took down the address of a brother, intending to call and apprise him of what he feared. On reaching his own home, two hours afterwards, a messenger met him, announcing that his patient had fallen into another paroxysm, soon after he left the house, and was dead. The body was carefully examined by a thorough anatomist, Mr. Stanley. There was no disease of the aorta,

or of the heart generally; but the coronary arteries resembled tubes of coral, being completely ossified as far as they could be traced.¹

The patient may even expire in the first or second paroxysm. This happened in the case of the late lamented Master of Rugby school.

You will perceive, from what has been said, that the prognosis of this singular and formidable affection is extremely unfavourable. The cases are very rare in which no disease of the heart has been detected: and the organic changes that have been found are remediless, and for the most part, progressive: and, in point of fact, the great majority of those who have laboured under the disease have died suddenly, and prematurely.

It follows also, as another corollary from the facts now brought before you, that there are very few cases in which we can dare to contemplate a cure. Our measures must be preventive when the paroxysms are absent: and our object will be to shorten the fit when it is present and protracted.

Now the preventive measures are simple and obvious. The patient must be cautioned to avoid the exciting causes of the paroxysm; walking up hill; or against the wind, which has also often been known to produce it. Whatever is likely to hurry the circulation, and therefore, among the rest, all mental emotion and anxiety, should be guarded against as much as possible. John Hunter died of angina pectoris: and the fatal seizure was brought on by a fit of anger. The very same precautions must be observed as those which I dwelt upon half an hour ago; and for the very same reasons. Care should be taken also to obtain and preserve a healthy state of the digestive organs. It is observable of this, as I told you before it is observable of other cardiac diseases, that they are often attended and aggravated by flatulence of the stomach and bowels. Persons labouring under a paroxysm of angina often experience great and sudden relief upon getting rid of a quantity of gas, by which the stomach had been distended. The flatulence acts, no doubt, by pressing the diaphragm upwards, and so diminishing the dimensions of the thorax, and impeding the play of the heart. It is upon the same principle that we must explain the fact, that the paroxysms are particularly apt to come on if the patient walks *soon after a meal*: also that they occur in the night, when he is in a horizontal position, and are relieved by his getting out of bed; that is, by his assuming the vertical posture, and taking off the pressure of the abdominal viscera from the diaphragm.

In the paroxysm itself, bleeding has been fairly tried: but, as I think might have been foreseen, it has seldom been followed by any benefit, and sometimes it appears to have done harm. The affection has a nearer relation to syncope, and often to syncope by asthenia, than to anything else. That is the way in which the patients die: and consequently, cordials, stimulants, and antispasmodics, are found to be of service. For the pain, when it is lasting as well as severe, the appropriate remedy is opium. Dr. Elliotson thinks prussic acid is the best thing you can administer. Dr. Davies has more faith in belladonna plasters than in most other things. Dr. Copland advises stimulant liniments externally; and warm carminative or aperient medicines, as the circumstances may require, internally. Hoffman's anodyne, under my own observation, has proved exceedingly useful. The general condition of the sufferer will suggest, I believe, the proper treatment. Not that it will suggest any particular drug, but it will teach you the main principle on which you are to proceed. If auscultation reveal any of those morbid states of the heart which were noticed in the beginning of the lecture, the means which I pointed out as suitable for remedying *them* may be put in force.

¹ The history of this case has since been published by Dr. Latham in his admirable *Lectures on the Diseases of the Heart*. He adds the important circumstance that "its (the heart's) muscular substance was more loose of texture than natural, but not softened in an extreme degree." He also gives a most interesting detail of Dr. Arnold's seizure and death: and he describes another instance, seen by himself, in which the period between the patient's first paroxysm and his last did not exceed ten days.

In this case "the muscular substance of both ventricles was so soft, as to be pierced through with the slightest pressure of the finger." In the spring of last year a well known baronet died in London of angina pectoris; the disease having run the whole of its manifested course in nine days.

LECTURE LXI.

Pericarditis: its frequent connexion with Acute Articular Rheumatism. Rheumatic Carditis. Anatomical characters of Acute Inflammation of the Pericardium; of the Endocardium. General symptoms. Auscultatory signs. Relations of Carditis with Rheumatic Fever.

I YESTERDAY considered, cursorily indeed, but as fully as the limits of these lectures will permit, the effects of hypertrophy, and of dilatation with and without hypertrophy, of the several chambers of the heart: and the means we possess of obviating or alleviating those effects. The chronic changes to which the *endocardium* is liable, especially in those parts where it covers the valves, and the tendinous rings that support the valves, were next reviewed; with most of the circumstances which give origin to such changes. Lastly, I spoke of that singular and perilous affection to which the name of *angina pectoris* has been applied. I proceed this afternoon to the diseased conditions of the *pericardium*. This membrane is often the seat of acute inflammation; and the consequence of such inflammation is sometimes, though rarely, the speedy extinction of life. But in nineteen cases out of twenty, the disorder proves fatal at a remote period; destroying the subject of it more slowly indeed, but almost as surely. Pericarditis is, therefore, and has always been regarded as, a very interesting disease; and the more so, that it is in many instances a very *insidious* disease also.

Acute pericarditis is liable to arise, like all other internal inflammations, after exposure to cold; or when no exciting cause is to be discovered. It sometimes follows blows received upon the chest; or other mechanical injuries. It is no uncommon result of a contaminated state of the blood, induced by that peculiar renal disease which I formerly mentioned as being one great source of General Dropsy also. But by far the most frequently of all does it happen, in connection with another complaint that we have not yet had before us—acute rheumatism; a febrile disorder, characterized by inflammation of a specific character, affecting the structures that lie around the joints, or enter into their composition—the *fibrous* tissues. I shall therefore consider acute pericarditis with reference to its occurrence in rheumatic fever; for in so doing I shall embrace all the practical points which belong to it under any form. But I must tell you that when *pericarditis* happens, in the course of an attack of rheumatism, so also, to the best of my belief, in almost every instance, does *endocarditis*. For this reason I shall include, in the account I am desirous to give you of *rheumatic carditis*, both these inflammations: inflammation of the investing membrane, and inflammation of the lining membrane of the heart. I mentioned in the last lecture, that, with respect to the latter, to *endocarditis*, there were some peculiarities noticeable, which I should reserve for the present occasion.

The pericardium is one of the serous membranes; so also may the endocardium be considered. But the pericardium is also a shut sac; and the primary effects of inflammation upon it are the same, *mutatis mutandis*, as upon the shut sac so near it, the pleura. The second series of effects is, however, much more formidable. Adhesion of the pleura does not necessarily abbreviate the natural term of the patient's life; adhesion of the pericardium almost always does: and effusion into the cavity that contains the lung is far less serious than effusion into the bag that surrounds the heart. In the one set of organs the mischief may be great, but it is *final*; in the other, it leads, in most instances, with unfailing certainty, sooner or later, to worse changes, which at length prove incompatible with the further continuance of life.

You will understand, then, without any necessity for my going again into much detail, that the pericardium, under acute inflammation, may undergo the same changes, which, on a former occasion, we saw that the pleura might undergo. Coagulable lymph may be poured forth from the entire membrane, and abolish the cavity by glueing the whole of the pericardium to the heart: or serous fluid may be effused, distending the bag of the pericardium, and keeping its smooth surfaces more or less

asunder: or both serum and lymph may be effused together: or fibrin, in some shape or another, may be *deposited*, for aught I know, from the homogeneous fluid which is thrown out by the inflamed membrane in the first instance; and the result of this mixed effusion may here also, as in the case of the pleura, be the *partial* adhesion of the membrane to the heart.

But in the majority of instances the inflammation spreads over the whole membrane, as it is apt to do in serous membranes generally; and one of these two things happens: either there is a large quantity of liquid effusion, which is not reabsorbed; and then usually the patient dies in a few days: or there is not much liquid effusion, or the liquid part is absorbed, and the pericardium becomes permanently agglutinated to the heart, and *apparent* recovery takes place.

In the cases that have proved fatal at an early period, when the inflamed membrane has been unadherent, it has been found to contain serous fluid; sometimes clear, oftener turbid, frequently tinged with blood; and it has been seen to be covered with a coating of the fibrinous or albuminous part of the blood; what we call plastic or coagulable lymph. The deposited lymph assumes a variety of forms in different cases; but in every case that I have seen, the prevailing character of the unattached surface has been that of *roughness*; and this is a circumstance of some importance, as we shall presently see. The lymph is not arranged in smooth layers; but it is rugged, villous, or cellular. According to the fancy of different observers, it has been thought to resemble lace-work, a sponge, a honeycomb, some kinds of coral, or the interior of a calf's stomach. Sometimes it bristles with a multitude of small, short, pointed papillæ; less frequently it is softer and shaggy; always it is rough and uneven. Dr. Hope, following Laennec, states that the surface looks something like that which would be produced by suddenly separating two flat pieces of wood, between which a thin layer of butter has been compressed. To my own eye, the appearance presented by the membrane, in its recent condition, has been more like the rough side of the pieces of tripe which you see in the butchers' shops, than anything else.

When, on the other hand, the patient dies, as he sometimes will do, soon after the whole of the membrane has become adherent, you will find the medium of adhesion to consist of lymph, in which a number of bloody points or streaks are visible: but still the connecting substance is soft, and the agglutinated membranes can readily be torn asunder.

Such is the state of things on the *outside* of the heart in such cases. But what do we find *within*? Why, here also, in *all* cases *probably*, certainly in by far the majority of cases, we may discover evident traces of inflammatory damage; and we discover them chiefly on the valvular apparatus. There does not appear to be such a tendency in endocarditis to diffuse itself over the whole membrane. Occasionally that naturally transparent portion of it which covers the muscular fibres is rendered whitish and opaque; and occasionally some of the deposits that are common on the valves, encroach also somewhat beyond them, and even stud, here and there, the interior of one or more of the chambers of the heart, and especially of the left auricle. But the valves or the fibrous rings from which they spring, are the parts first and chiefly implicated, especially the aortic valves, and the mitral valve, not uncommonly the tricuspid valve also; and sometimes even the semilunar valves of the pulmonary artery. Inflammation thus affecting both the external and internal membranes of the heart, in acute rheumatism, I would call *rheumatic carditis*.

The inflamed valves undergo two kinds of change, distinct from each other. They become thicker than natural; they lose their transparency and pliancy, and are puckered. These changes depend upon the deposit of lymph *beneath* the membrane;

Fig. 86.

Pericarditis, showing the appearance of recently effused lymph. From a specimen in Dr. Gross' cabinet.

between the membrane and the fibrous substance which it covers. Sometimes they are folded down, and glued, as it were, to the opposite surface. This must be by coagulable lymph deposited on the *outer* side of the membrane. But more frequently than all, they present more or fewer of those wart-like excrescences, or fleshy granulations, which I spoke of in the last lecture, and which are of course *upon* the free surface of the membrane. Sometimes these vegetations are scattered irregularly over the convex surface of the valve, or in its immediate neighborhood; much oftener they have a more definite and curious distribution; an arrangement which I have never seen noticed by any author, but which it has been my lot so many times to observe, that it has led me to remark an anatomical peculiarity with which it is connected; and this piece of minuter anatomy I have looked for in vain in books, and I have in vain sought information about it among all the anatomists of my acquaintance. They none of them have seemed to be aware of it, though they acknowledged that the fact was so when I pointed it out to them. Recently, indeed, I have been told that the peculiarity of structure to which I allude is somewhere adverted to by Morgagni.

It becomes necessary, therefore, that I should describe to you this discovery of mine (if it deserve so grand a name), as I have, for several years past, been in the habit of showing it to the pupils of the hospital in the dead-house. It derives its chief interest from the light which it throws upon the morbid appearances to be spoken of presently. You will find, then, if you examine closely the semilunar valves of the aorta, or of the pulmonary artery, that in each valve there may be distinguished two parts; one thicker, the other thinner. The thicker part lies next the base of the valve; the thinner next its edge. And the valve does not become thin by degrees, but the difference is marked by a manifest line of separation between the thicker and thinner portions; and this is not a straight, nor even one sweeping curved line, but it forms a double curve. It consists of two semicircular lines, running each from the centre of the edge of the valve, from the sesamoid body there situated, to either extremity of the edge, where the edge joins the side of the aorta. So that there are two segments, of a crescentic shape, thinner and less opaque than the remaining part of the valve, and lying near its free margin. This peculiarity of structure is uniformly present. It is less distinctly visible in the valves of the pulmonary artery than in those of the aorta; and it is much less apparent in some individuals than in others; but it is always to be seen when it is looked for.

The anatomical account of this arrangement is not far to seek. The cardiac valves consist of a loose duplicature of the delicate endocardium, between the folds of which is received a thin prolongation of fibrous tissue, from the tendinous rings surrounding or constituting the several orifices that are furnished with a valvular apparatus. In the semilunar valves this fibrous substance does not interpose itself between the entire space of the folded membrane. It reaches the free edge of each valve at three points only; namely, at the centre, where it forms the *corpus Arantii*, and at the two extremities. Between these points it stops short, and has a definite limit and outline; a scalloped edge: and so leaves two crescentic portions of the valve formed merely by the doubled endocardium. The crescentic margins are thin and transparent: the remaining shield-shaped portion of the valve is more or less thick, firm, and opaque.¹

And the physiological reason of this arrangement is also apparent enough; though I failed to perceive it until it was explained to me by Mr. Thurnam. Each valve, when opened out, is convex towards the ventricle. The three valves do not merely meet by their edges. Their common purpose would be but insecurely provided for if such were the case. They meet and bend up, and come broadly into contact with each other. Each valve during the diastole has its right and left crescentic portion applied respectively to the corresponding portion of its right and left fellow valves. The thin segments are pressed mutually together, and lie *dos-à-dos*, as dancers say; while their edges look in the direction of the vessel. All this you may convince yourselves of by injecting the aorta of an ox with wax, and picking out the wax when it is cold.

Now the curious fact which first led me to remark this natural structure is, that

¹ This formation of the arterial valves is described and delineated by Morgagni, in his *Adversaria Anatomica*; as Dr. Todd, since the publication of these Lectures, has been good enough to point out to me.

the minuter vegetations, which form upon the aortic valves, in acute rheumatic carditis, most commonly arrange themselves in a row, like a string of beads, along the line of union between the scalloped edge of the thicker scutiform portion of the valve, and the inner convex margin of the two thinner crescentic portions. Sometimes they follow that double festoon very exactly and completely: sometimes the continuity of the line is broken, and the excrescences straggle from it a little; but still the general tendency to adhere to it is evident. No one that I know of has publicly noticed this fact; yet that it is a fact, a good many persons, who have been for some time about the Middlesex Hospital, are perfectly aware. The truth is, that death seldom happens early in these cases; and perhaps the valves have not always been carefully examined when opportunity did offer. My friend, Dr. Latham, had been watching for such a case in vain for some years. At length, however, two of his hospital patients died in the first attack of rheumatic carditis; and he tells me that, looking with great interest for the morbid appearances within the heart, he found them such as I have been stating. I have chanced to see six or eight such early fatal cases.

The arrangement just described is the most common one, so far as the aortic valves are concerned; but sometimes even there, and generally upon the mitral and the tricuspid valves, the little wart-like excrescences have a different position; jaggling the free edge of the valve with numerous fine serræ, like the teeth of a small saw; or being disposed, just within its border, in one continuous line.

After what has been said, you will readily detect the physical cause of this curious distribution of the wart-like excrescences. The membrane suffers inflammation. Soft lymph exudes from it, or is deposited upon it; and as fast as it is formed or deposited, it is pressed aside, by the repeated concourse of the opposed surfaces, from the crescentic portions of each valve; and heaped up along the boundary lines of contact; just as a thin layer of butter on a board would be displaced, and heaped up in a little curvilinear ridge, by the pressure of one's thumb. The double festoon, and the little marginal teeth, are obviously both formed in this way.

If my verbal description has been insufficient to make all this clear to your apprehension, the drawings before you speak, I hope, in plainer language.

These, then, are the appearances commonly seen within and without the heart, when the patient does not long survive the first attack of rheumatic carditis. When death takes place at a later period, you find more than this. You find the consequences which flow from these primary lesions, operating as mechanical causes of further change: hypertrophy and dilatation in their various degrees and combinations; or, sometimes, atrophy.

You will please to bear the primary changes in mind; for they satisfactorily account for the *physical signs* of pericarditis and endocarditis which are displayed in these cases, and which I shall describe and explain after I have shortly inquired into the *general symptoms*.

The symptoms, then, of pericarditis, as set down by authors, and such as I have myself frequently noticed, are the following. There is often, very early in the disease, a singularity of manner, and peculiar expression of countenance, difficult to describe, yet strikingly manifest to the observer; a strangeness of deportment mixed somehow with an aspect of distress. To this are frequently added, pulsation within the chest; a sense of oppression in the epigastrium; a catch in the breathing; a dry cough; inability or unwillingness on the part of the patient to lie on his left side; pain in the situation of the heart, increased by a full inspiration, by pressure upon or between the corresponding ribs, and more particularly increased by pressure upwards against the diaphragm by means of the fingers thrust beneath the cartilages of the false ribs; stiffness and pain in and about the left shoulder, and extending thence down the left arm, and stopping short perhaps at the elbow or wrist. This last circumstance, however, the pain shooting down the arm, is more common in *chronic* affections of the heart. Sometimes jactitations occur, like the jactitations of chorea. And I have yet another symptom to mention, and a very important one; and that is delirium, sometimes quiet, but often wild and furious delirium, not dependent upon any disease of the encephalon.

Of course there are also the febrile symptoms which accompany the acute rheuma-

tism; or if the pericarditis occur independently of acute rheumatism, there will usually be fever symptomatic of the local inflammation.

Now each of these symptoms I have repeatedly observed; but they seldom all concur in the same case. If they did, there would not be much difficulty in the diagnosis: nor would the cardiac disease be so often overlooked as it is. The diagnosis of pericarditis has been confessedly uncertain and obscure. Not unfrequently, nearly all the symptoms that I have been enumerating are wanting; or are so indistinctly marked as to attract no attention. It is therefore an important matter to ascertain what help we may derive, in these equivocal cases, from auscultation.

In truth, the help which we sometimes get is peculiarly valuable and satisfactory. There are characteristic morbid sounds to be heard when the heart is beginning to labour under rheumatic carditis.

The morbid sounds which may reach the ear applied in such cases to the surface of the chest are two: very distinct the one from the other, and very distinguishable; depending upon different causes, and denoting diversities of operation and of site in the morbid processes going on within. But they are not both audible in all cases.

One of these sounds I have been accustomed to call a *to and fro* sound. It conveys to the ear the notion of the rubbing of two rough surfaces, backwards and forwards upon each other. It seems near to the ear; and therefore near to the surface of the patient's body. Like all the other morbid sounds heard within the chest, it is capable of much variety in tone and degree. Sometimes it very closely resembles the noise made by a saw in cutting through a board. Sometimes it is more like that occasioned by the action of a file, of a rasp, of a nutmeg-grater. But its essential character is that of *alternate rubbing*; it is a *to and fro* sound. This very peculiar sound I had noticed and described, and explained, before I was aware that it had attracted the attention of any other persons. Others, however, had remarked it, and had correctly interpreted its meaning. I claim no credit therefore for the discovery of what I think a very important symptom: but I claim for the symptom itself that additional weight which accrues to it, from its having been originally perceived by different observers, independently of each other. The physician who, in this country, without my being aware of it, had noted and published some cases in which this phenomenon occurred, is Dr. William Stokes, of Dublin. There is a good deal said about it by Bouillaud also; and he too appears to have discovered the sound, without any previous knowledge of its having been noticed by others. I have heard the *to and fro* sound now in some scores of cases. In a few of these it never ceased except with life. The patients died during the primary attack, and the *to and fro* sound remained as long as the heart continued to beat. In all the other cases, the *to and fro* sound was audible for a few days only, and then ceased entirely, and probably for ever: the patients recovering more or less completely.

The other of the two morbid sounds, is the ordinary bellows-sound, with which you are already familiar. In the case in question it is a single sound; a deep-seated rush, or whiz, accompanying the systole of the heart. It usually continues long; often for life.

These two sounds, the superficial *to and fro* sound and the deep-seated bellows-sound, may sometimes be heard, by a careful listener, to exist together. Sometimes the bellows-sound begins to be distinguished when the rubbing sound ceases; appears to supervene upon it, or to take its place; perhaps it then first becomes audible, simply because it was previously drowned in the louder superficial sound. Sometimes there is no *to and fro* sound, but only the deep blowing noise; or (what in many cases is extremely probable, nay, what I may venture to say is certain) the *to and fro* sound has *come and gone* unnoticed—unlistened to.

Now of these sounds, which I repeat are perfectly distinct, and capable of being easily discriminated the one from the other, the first mentioned, viz., the *to and fro* sound, is always indicative of inflammation of the *external* membrane; the other, the bellows-sound, is always, as I believe, in these cases, indicative of inflammation of the *internal* membrane of the heart. You will bear in remembrance, that I am speaking of these sounds as they somewhat suddenly occur for the first time, and especially as they are apt to occur in *rheumatic carditis* at its *first* accession.

Those of you who have seen the thorax opened in an animal whose heart still continued to palpitate, may have observed, as I have done, that the pericardium lies

closely in contact with the heart, but that a considerable extent of slipping motion between them goes on at every successive act of systole and diastole. They glide over each other evenly and without noise; but this is only while the surfaces are smooth and healthy. When they are already made rough by inflammation and the deposit of lymph, which lymph always, as I have shown you, is rough in such cases, then the attrition will be no longer noiseless: it will give rise, in the alternate movements of the organ, to the harsh and superficial *to and fro* sound. But why does that sound, when once it has occurred, at length cease; and why, having once ceased, does it never by any accident, when the inflammation has been universal, recur? Clearly because the pericardium has become adherent to the heart: after which there can be no motion of the one membrane upon the other, and therefore no sound indicative of such motion.

That this is the true explanation of the occurrence, and of the permanent cessation, of the *to and fro* sound, I am now (March, 1837) convinced. It was a matter of inference with me for some time. A few of the patients died during the primary attack. By much the majority recovered. I do not mean got perfectly well as they had been before; but they regained a great share of their usual health, perhaps seemed, and *thought* themselves *well*, and left the hospital where they had been under treatment. Now, of those who died, the pericardia were non-adherent. The opposite surfaces of the membranes were rough, and like tripe: and the *to and fro* sound never ceased in these persons. Such cases are always soon fatal. But, in the others, did adhesion take place? I make no doubt of it. Within the last twelve months I have had demonstrative proof of it in two instances. One of these occurred in a hospital patient, whose case has been published in the *Medical Gazette*.¹ He was a painter, nineteen years old; and he became my patient last May, with acute rheumatism and earditis. From the 26th of May to the 13th of June, a *to and fro* sound was distinctly audible, as well as a bellows-sound which had preceded it. After that date, the bellows-sound continued, but the rubbing sound was no longer to be heard. The patient improved; and was about to be discharged from the hospital: when, on the 29th of June, sixteen days after the sound of friction had finally ceased, he suddenly dropped down dead in the garden of the hospital.

Here I had concluded that the pericardium was adherent; though I had not expected to have so soon the opportunity of verifying my opinion. And accordingly, except over a small portion of the posterior part of the right ventricle, the union between the heart and its investing bag was complete at all points. The agglutination was evidently the work of recent disease. The medium of adhesion was of considerable thickness; and consisted of coagulable lymph, and coagulated half-organized blood. The pericardium was stripped off, as I have seen a poulticer skin a rabbit, and with about the same ease. This was a very interesting case to me, for it was the first in which I had had the privilege of examining the heart after having witnessed the peculiar succession of phenomena that I have been describing.

But since that time, I have met with another such case in private practice. The particulars of it are sufficiently important to warrant my relating them.²

In the month of October, 1836, I was taken by Dr. Sweatman to see a patient of his; whom I found sitting up in bed, pale, with sharp features, breathing shortly and laboriously. His legs were anasarcaous, and his belly was tense and fluctuating.

I learned that he had been for years given up to intemperance in drinking, and to indolent and low habits. He told me, that the wind troubled him, shooting up through the whole of the left side of his chest. On further inquiry I found his meaning to be that he had much pain there. There was loud wheezing over the upper lobes of both lungs: both sides of the thorax were dull on percussion at their lower part; and on the right side no breathing whatever was audible below. These latter symptoms were indicative of dropsical effusion into the pleura also. The jugular veins were swollen and tortuous on both sides of the neck. On applying my ear to the præcordial region I at once heard a very loud and distinct *to and fro* sound. This was equally manifest when he held his breath. Dr. Sweatman, who was not so much accustomed as I have been to listen to the sounds of the heart in disease, recognised instantly the peculiar character of this sound. I ventured to express my

¹ Vol. xviii. p. 701.

² *Medical Gazette*, vol. xxi. p. 544.

certain conviction, that the patient was labouring under recent and acute pericarditis. I added, that he had also hydrothorax; and that, whatever chronic changes might have taken place in his heart previously to his present illness, dilatation of the right cavities constituted at least one of them.

He had been attacked by his present urgent symptoms three days before I saw him, viz., on the 8th of October. On that day, in all probability, the inflammation of the pericardium commenced.

This was his history. In the spring of the year, having, from indolence, kept the house for months before, he crossed from the Isle of Man to Liverpool, and was sick, and suffered a good deal during the passage. After landing, he had a mile or more to walk. His companions outstripped him, but were called back to him, and found him very pale, breathing with difficulty, and unable for a time to proceed. He attributed all his subsequent complaints to that exertion: and he had been ailing, though not confined to his room, till the 8th of October. I did not venture, in his condition, to open a vein: but leeches were applied to the præcordia, and he took diuretics.

I did not see him again till the 15th of October, four days after my first visit. The rubbing sound was still there, though less loud, less harsh, and less extensive. The leeches had given him much relief. His pulse was very small. A blister was now applied. On the 20th, I saw him for the third and last time alive. The rubbing sound was quite gone. Of this Dr. Sweatman also satisfied himself. There was a dull systolic bellows-sound in its place. The pulse was scarcely perceptible: but he continued apparently improving, making a vast quantity of urine, while the dropsical swellings fast diminished, till the 31st; when, after talking a short time oddly, and in a peculiarly loud voice, he sat up to take some medicine; and having done so, reclined his head against the nurse, and expired. Mr. Shaw assisted in the subsequent examination of the body. I omit giving an account of the condition of the lungs and pleura, which was what we had anticipated; and confine myself to the state of the heart. That organ was large. The pericardium was adherent universally by means of lymph, mottled with blood: and it was easily separated, so that the adhesion must have been recent; as was proved indeed by the symptoms. The right cavities of the heart were very large; and the aorta was diseased.

The existence of the *to and fro* sound in these cases no one can doubt who has once listened for it when present: and the facts respecting it, which have been established beyond the reach of controversy, are these:—1st, That when it occurs *de novo*, it always and surely denotes acute inflammation of the pericardium. I say *de novo*, because (as I stated in the last lecture) a *bellows-sound* may accompany *each movement* of the heart, in consequence of *internal* disease of some standing; and this double, sawing, bellows-sound might possibly be confounded with the alternating noises produced by the attrition of the opposite surfaces of the inflamed pericardium. If any doubt should ever arise in your minds respecting the meaning of sounds which are sometimes thus similar in character, while they result from very different conditions, it may aid your diagnosis to remember, that endocardial murmurs are often plainly traceable along the course of the great arteries of the thorax; and that the exocardial rubbing sound, though it may be audible over nearly the whole of the chest, is not heard with any special distinctness in the arteries. 2ndly, The *to and fro*, or rubbing sound, is never of long duration, but soon terminates in one of two ways. Either the patient dies in a short time, the sound continuing to the last; and then the pericardium is found coated with rough lymph, but throughout the far greater part of its extent, or altogether, *unadherent*: or the sound ceases, never to return, while the condition of the patient improves; or he even seems to himself and to others, to recover his perfect health. In these cases, the sound ceases from a physical impossibility of its continuance, viz., from adhesion of the pericardium over the whole, or the greater part, of the surface of the heart. And in this category of apparent but unreal recoveries, I cannot doubt that many of Bouillaud's cases of "*pericarditis terminating in health*" ought to be included.

It follows as a necessary consequence from these facts that acute and general pericarditis, so far advanced as to occasion the pathognomonic rubbing sound, does not admit of a perfect cure: and that its best event is the adhesion of the membrane, and the obliteration of its cavity.

And even then, I say, the change is not final. An adhering pericardium does so embarrass the movements of the heart as to cause at length, sometimes rapidly, sometimes slowly, further changes, affecting the muscle thus held in its morbid embrace. It has indeed been shown, by Dr. Barlow and Dr. Chevers, that this restricting cover has no direct tendency (as had commonly been supposed, by myself among others) to produce hypertrophy. On the contrary, when the adhesion takes place during youth, as in connexion with acute rheumatism it is very apt to do, it seems to prevent the further growth of the heart, and virtually leads to atrophy of that organ, or a disproportionate smallness of its cavities, vessels, and general size. Dr. Barlow points out a mode in which simple adhesion of the pericardium may indirectly bring about hypertrophy of the right ventricle, through its influence upon the functions and development of the lungs. Instances are numerous, however, of considerable hypertrophy of the left chambers, and of the whole heart, co-existing with an adherent pericardium. But in these cases the hypertrophy is really due to the impediments opposed to the free passage of the blood by valvular or other endocardial disease. It is held, too, and I believe justly, though I am not so sure of this as of some of the other points I have been dwelling upon, that the inflammation which begins in the membrane sometimes dips into the muscular substance of the heart, weakens its elasticity and cohesion, and so leads ultimately to dilatation of its cavities.

I need not occupy much of your time in speaking of the other morbid sound that is audible in these cases, the bellows-sound: which sometimes may be heard before the to and fro sound commences; which I have frequently heard *through the to and fro* sound; and which often remains after the superficial rubbing sound has ceased. This depends, no doubt, upon those alterations in the lining membrane, and especially in the valvular apparatus of the heart, which take place from inflammation, at the same time with the alterations of the pericardium. And when it is met with in such cases, it may be set down as indisputable evidence of the existence of endocarditis.

I am anxious that you should take an interest in the disease of which I have been speaking at so much length this evening, and that you should keep it in mind in your future practice: for I am certain that it is a fertile, but often unsuspected source of chronic disease of the muscular substance of the heart, and of its consequences; asthma, dropsy, sudden death. The number of patients that come into the hospitals of London affected with acute rheumatism is annually very large: and I am sure that I do not exaggerate when I say that more than one-half of them have the heart or its membranes implicated. The cardiac affection may easily be overlooked both by the patient and the physician. The recovery may appear to be perfect. But after some time, palpitation begins to be occasionally felt; and, by degrees, other symptoms, marking disease of the heart, declare themselves: but their origin is unsuspected or forgotten. You will be surprised, if you search back into the past history of all the patients who apply to you having disease of the heart, especially among the lower classes of society,—you will be surprised to find how many of them will acknowledge that at some time or other of their lives they have been laid up with rheumatic fever.

It is no part of my purpose to treat at present of that specific disease of the joints to which we give the name of acute rheumatism: but I may as well complete what I have to say of carditis as it occurs in connexion with that disease; and then I shall not need to repeat myself when I come at length to rheumatic fever.

In the first place, then, I would say a few words more respecting the nervous disturbance which is apt to supervene in such cases, and to mask the real disease, and to mislead the unwary practitioner. Patients labouring under rheumatic carditis very frequently become affected with delirium, or violent mania, or stupor and coma, or convulsions, or all of these in succession; and you might suppose that they were labouring under inflammation of the brain, or spinal cord; or of their membranes. Such cases are in fact spoken of as cases of *metastasis* to the brain. It may sometimes be so, nay, I know that it sometimes is so; but not often.¹ Again and again,

¹ The accuracy of this statement has been questioned. It was founded upon the single instance of a female patient of my own, who died in the Middlesex Hospital after symptoms of cerebral inflammation, supervening upon acute rheumatism. Unequivocal pus was found smeared over the hemispheres of her brain. In the 29th volume of the *Medical Gazette*, Dr. Fyfe of Newcastle has related the history of a very similar case; a third example is recorded by Dr. Fuller, as having occurred in St. George's Hospital under the care of Dr. Seymour.

when death has occurred, and the delirium had been extreme, no traces of disease have been discoverable within the skull, nor within the vertebral canal, while marks of violent and intense inflammation have been visible in the pericardium. It may be that the acute cardiac affection interferes somehow with that regulated supply of blood to the head, which is necessary for the due performance of the cerebral functions. It may be that a morbid quality of the blood itself disturbs them. It may be that the cerebral or spinal symptoms are purely reflex phenomena, of eccentric origin, and excited by the irritation of incident nerves, pertaining to the heart. Whatever the explanation, recollect the fact; and whenever, in acute rheumatism, you find your patient flighty and wandering, or more distinctly delirious, or affected with any form or degree of convulsion, examine carefully the condition of his *heart*.

As this is really a point of great importance, and as you will not find much information respecting it in books,¹ I shall take leave to quote, here, some part of a clinical lecture delivered by myself at the Middlesex Hospital, in the year 1835, and printed in the 16th volume of the *Medical Gazette*. My subsequent experience has been quite in conformity with what I then stated.

"The functions of the brain not unfrequently become disordered in rheumatic fever: and disordered in such a manner and degree as would lead, and has led, many to believe in the presence of active inflammation of that organ, or of its enveloping tissues. Yet this affection of the brain is not, I believe, inflammation, but some secondary affection of the circulation therein; resulting from disturbance at the central organ of the circulation; capable of producing a corresponding derangement in the cerebral functions. I can best explain what I mean by reciting a few examples.

"The first case of this kind that I ever saw or heard of, occurred in St. Bartholomew's Hospital, many years ago. I took notes of it at the time, and will read you the substance of them. Charlotte Rankin, aged 17, was admitted there on the 12th of August, 1824, under the care of Dr. Roberts, with acute rheumatism of the joints. Her illness had come on suddenly a week before, after unusual exposure to cold and wet. The pain and swelling had shifted much from joint to joint. She had been bled, on account of pain in her left side, two days before admission. On the 14th, she complained of much difficulty of breathing, and of pain when even slight pressure was made upon the chest. These symptoms were entirely removed by a blister. On the 16th, she was observed to be odd in her manner — peevish, querulous, restless, without sleep, and desirous of getting out of bed. Her pulse was then 100. On the 20th the pulse had risen to 120; it was quite regular. She said she felt no pain, except the soreness occasioned by the blister. She slept very little. On the 21st, the pulse was 128. Some jactitation of the left arm was now observed, which, she said, had never happened before. No sleep. On the 22nd, about nine in the evening, she became furiously maniacal, and it was necessary to confine her by a strait-waistcoat. She continued in that state for upwards of four hours, and then died.

"Twelve hours afterwards the body was examined. The brain was found quite healthy: its vessels seemed, indeed, somewhat fuller of blood than is usual, but there was no effusion, nor any other vestige of inflammation.

"The pericardium was glued to the heart, in several places, by recent adhesions; and it was universally coated, where not adherent, by a layer of rough reticulated lymph, remarkably harsh to the touch.

"Now here the most prominent symptoms were such as we are accustomed to refer, with tolerable confidence, to inflammation of the membranes of the brain; whereas, in fact, the inflammation was strictly confined to the heart. If no examination of the body had been made, the case might have been quoted, with much show of reason, as a well-marked example of metastasis to the brain. It was so considered, before the brain was inspected.

"There had, indeed, been symptoms which indicated, and that not obscurely, the cardiac disease. At that time, however, I did not know how frequently carditis is

¹ This statement is no longer true. Dr. Burrows has fully considered it in his valuable essay, published in 1846, *On Disorders of the Cerebral Circulation, and on the Connexion between Affections of the Brain and Diseases of the Heart*. It is gratifying to me to find in Dr. Burrows' observations upon this interesting subject so striking an accordance with and confirmation of my own, which at that time had not fallen under his notice.

combined with acute rheumatism. Auscultation had not yet come much into fashion in this country; at any rate, I knew little or nothing of its use; and I had supposed (and it had been supposed by others who witnessed the case) that the chest symptoms resulted from rheumatism of the intercostal muscles.

"Another instance, in which the course of the symptoms was somewhat different, yet equally calculated to mislead, you have lately seen in this hospital.

"William Wilkins, a post-boy, 28 years old, was admitted on the 25th of last November.

"He complained of pain in most of the large joints, shifting from one joint to another. There was no visible redness or swelling, but he had much fever. The pain was greatest at night. He had profuse perspirations, during which the pain was not mitigated.

"He had been ill eight weeks; and at first his joints (according to the statement of his friends) were both swelled and red. He appeared to be recovering at one time, but relapsed. For three or four days previous to his admission he had coughed a little, and spoken of pain at the pit of his stomach. He lay more comfortably on the right than on the left side, but this was habitually the case. He had never had acute rheumatism before.

"He raved a good deal during the night of the 26th, and on the 27th he began to refuse to take his medicine, appeared confused and stupid, and answered questions tardily and imperfectly. He was bathed in perspiration, which had the strong acid smell so common in cases of acute rheumatism.

"During the next ten days he remained in a singular state of quiet delirium, rejecting medicine and food, saying he had had enough; getting out of bed, especially in the night, and declaring that he was going home. When questions were put to him, his lips moved, and his limbs began to stir and fidget, as though he were about to answer; yet he said nothing. He understood what was said to him, and put out his tongue when desired so to do; imperfectly, however, and with slowness and apparent difficulty. His bowels were costive, and he passed his stools, when purgatives acted, in the bed. His pulse was small and frequent; and when his wrist was taken hold of that the artery might be felt, he always resisted, and forcibly contracted his arm.

"Then for three or four days he appeared to improve; his countenance became more clear and lively; but he still showed the same restlessness, and maintained the same dogged silence when spoken to, and obstinately refused to swallow medicine. He was somewhat cunning, too, for he would take pills into his mouth, and then, when he thought he was not observed, chew and spit them out again.

"His pulse became at last very frequent, and his strength diminished rapidly. He died on the 18th of December, and the body was examined on the following day.

"The cerebral veins were gorged with dark blood, and there was a considerable quantity of serous fluid beneath the arachnoid, and in the lateral ventricles.

"The pericardium was free from disease; but upon the mitral valve, near its edge, there was a perfect row of small, slender, bead-like warts.

"A few weeks ago I was consulted in a case of a similar nature, which occurred in the practice of a gentleman who was formerly a pupil here, and who was fully aware both of the frequent occurrence of carditis in acute rheumatism, and of the anomalous symptoms with which it is sometimes attended. The patient was a young man, 24 years of age.

"On the 22nd of December he was seized with pain and swelling of several of the larger joints, and with fever. The attack was ascribed to exposure to cold the day before; he had previously enjoyed perfect health. The inflammation shifted rapidly from one joint to another. He was confined to bed for six days: then feeling better, he got up, changed his room, and presently underwent a relapse. Mr. Elwin tells me that, after that time, he was never comfortable about this patient; his countenance was pale, and his aspect unpromising; his pulse frequent; and more than once he complained of slight pain in the epigastrium, increased by a full inspiration. This was removed by a mustard-poultice. No morbid sound was detected upon a careful examination of the præcordial region by the ear. He remained low-spirited, but slowly mending, till the 3rd of January, when in the evening, without any notice or obvious cause, he began to be restless and delirious.

"On visiting him the next morning, Mr. Elwin found him with an anxious countenance; a frequent and irregular pulse, which occasionally intermitted; his mind wandering; the action of his heart strong, and attended towards the sternum with a loud bellows-sound. The next day his breathing was difficult, and 'catching;' the pulse 120, hard and wiry. At that time I had the opportunity of seeing him. He was lying in a sort of stupor, yet not unconscious, for he put out his tongue at my request, and answered pertinently one or two questions, after they had been frequently repeated. He had the air of a person obstinately determined to say as little as possible. He became more distinctly delirious towards evening; and the next day his pulse and breathing were both so frequent (148, and 78, in the minute, respectively) that he was thought to be dying. A distinct bellows-sound was audible near the left mamma. This state continued, with slight fluctuations, till the 8th, when his condition appeared somewhat more hopeful. He was calm, had no dyspnoea, and conversed more readily, — saying sometimes that he felt as if he were 'dead;' sometimes that he was 'burnt up.' He complained, for the first time, of pain in the right temple; his gums were slightly under the influence of mercury; his pulse scarcely exceeded 100; the bellows-sound was very manifest.

"On the 9th he again became, first restless, and then violently and wildly delirious, screaming out, refusing to take medicine, or to open his mouth when it was offered; yet he evidently knew what was said to him. During the night general convulsions came on in occasional spasms, of a tetanic character: in the intervals between them he lay in a state of coma. He survived in this condition till the 12th.

"I was present at the inspection of the body ten hours after death. Some of his family insisted on being in the room with us; but we were able to make an accurate examination of the head, and of the heart.

"The veins of the brain seemed somewhat fuller of blood than is common. The arachnoid was slightly elevated by a clear serous fluid collected in the pia mater. There was but a small quantity of a similar fluid in the lateral ventricles. The lungs appeared quite healthy.

"There was no fluid in the pericardium. Its surface was everywhere exceedingly vascular, but it presented no appearance of lymph, except where it adhered to the posterior side of the heart, over a space of about two inches and a half in length, and upwards of an inch in breadth. The lymph which formed the medium of connexion was firm, but evidently of recent formation; and a very slight degree of force sufficed to separate the adhering membranes. The heart was rather small, and the left ventricle had a singular wrinkled appearance externally. Towards the edge of the mitral valve there was a profuse crop of little wart-like vegetations, of the size of millet-seeds, and numerous red lines converged towards them from the base of the valve. The aortic valves all presented curious festoons of similar excrescences, larger, however, and more prominent, than those upon the mitral valve.

"In the beginning of the year 1832, a girl nineteen years old, Frances Kirk by name, was a patient of mine in the hospital, with acute rheumatism of the joints, and carditis, manifested by many of the most usual symptoms — by pain in the situation of the heart, dyspnoea, great frequency of pulse, and a distinct bellows-sound. She lived two months from the commencement of the cardiac disease. During that period she was at times wildly delirious — at times stupid, taciturn, and almost idiotic — and at times quiet and rational. The brain in that case was found perfectly healthy, except slight serous effusion beneath the arachnoid. The pericardium was everywhere adherent to the heart. By some mismanagement the opportunity of inspecting the inner membrane of the heart was lost.

"In each of the three last-mentioned cases there was more or less serous fluid found in the meshes of the pia mater, and in the lateral ventricles. You may ask, perhaps, whether this effusion was not good evidence of previous inflammation there? whether it did not show that the metastasis, which I have spoken of as seldom happening, really did happen in these very cases?

"I apprehend not; and for the following reasons.—In one only of these cases was the amount of the serous accumulation at all considerable. There was no other trace of inflammatory action in any of them; no redness, nor pus, nor lymph; none of the *unequivocal products* of inflammation. What quantity of serous effusion beneath the arachnoid, or in the ventricles of the brain, is requisite to establish its morbid origin

— within what limits such effusion may be considered natural — whether it may not be ascribed wholly, or in part, to mechanical transudation after death; these are questions which have not yet been definitely settled among pathologists. For my own part, whenever I see the veins of the pia mater full of blood, I *expect* to find serum between that membrane and the arachnoid. How much of it may have been poured out before death, and how much afterwards, it would be difficult to estimate. In each of the cases before us there was evidence, not to be mistaken, of cardiac inflammation. Now that acute inflammation, fixing itself upon some portion of the heart, should embarrass its action, and modify the condition of the circulation through the cerebral blood-vessels, is not only conceivable, but highly probable. Any retardation of the venous circulation in the head — any engorgement or congestion of that system of vessels — would be likely, if we may reason from the analogy of other parts, to produce effusion. I have seen, in the brain of a criminal who had been hanged while in a state of perfect health, as much serum collected in the same parts as we found in the patients whose cases I have been relating. It is possible that, in them, the disorder of the sensorial functions depended upon simple disturbance of the cerebral circulation; it is possible that the same disorder depended upon the serous effusion; and it is possible, and (I think) probable, that it depended in part upon both these causes. It is very certain that similar symptoms have occurred in similar cases, when there was no appreciable effusion; and, apparently from mere derangement of the natural circulation of the blood in its vessels. On the other hand, we know that an equal, or a greater amount of effusion, has often been observed, when no such cerebral symptoms had manifested themselves. I conceive, therefore, that the symptoms referable to the brain, and the quantity of serum found effused there (whether these bear to each other the relation of cause and consequence, or not), are both to be regarded as secondary effects of the cardiac disease; that they denoted no inflammatory condition of the brain, or of its membranes, but were the common result of that inflammation of the heart, concerning the existence of which the inspection of the bodies left us no room to doubt.

“That this view of the matter is correct, is the more probable because (as I just now stated) the same symptoms have been known to accompany carditis, although no serous effusion was met with in the head. There was none in the case of the girl Rankin; none in a case related by Dr. Davis; none in a remarkable case detailed by Dr. Latham; none in a striking example of a similar kind which fell under the observation of that accurate and most accomplished pathologist, Andral. I shall take the liberty of citing these two instances.

“‘One of the children of Christ’s Hospital,’ says Dr. Latham, ‘had, in the opinion of all who saw him, the severest inflammation of the brain. The attack was sudden, with great heat and frequency of pulse. He had delirium and convulsions, and pointed to his forehead as the seat of his pain. In three days he died, and, upon dissection, not a vestige of disease was found within the cranium; but the heart was exclusively the seat of the disease, and no other part of the body discovered the slightest morbid appearance. The disease of the heart was not confined to its investing membrane. It was the most intense inflammation pervading the pericardium and the muscular substance.’

“Andral’s case, which is referred to by Dr. Latham, occurs in his *Clinique Médicale*.

“A woman, twenty-six years old, was brought to La Charité, in a state of delirium, and no account could be obtained of her previous condition. The delirium was remarkable for the obstinate taciturnity which attended it. When questioned, the patient turned a fixed gaze upon the person who spoke to her, but made no reply. Her face was pale; her pulse small and frequent. During the two following days the head was frequently drawn backwards, the trunk was shaken at intervals by convulsive movements, and she had subsultus tendinum; but she now spoke, and appeared to comprehend what was said to her, but talked incoherently. The pulse was very frequent, and intermitting. On the fourth day the delirium ceased; she complained of nothing but great debility. The muscles of the face were almost continually agitated by convulsive twitchings, and the arm from time to time presented a sort of tetanic stiffness. On the fifth day the delirium returned; the patient then fell into a state of coma, and died the next morning.

"Neither the brain, nor the spinal marrow, nor their membranes, presented any appreciable morbid appearances. The pericardium was lined with coagulable lymph, and its opposite surfaces were connected, in some places, by recent bands of adhesion. It contained also some ounces of a greenish flaky serum. No other trace of disease was discoverable.

"Now if you are not made aware beforehand of this strange course of the symptoms arising, sometimes, out of rheumatic carditis, you will be apt to overlook the cardiac affection, and to direct your remedial measures wide of the mark. In a second instance mentioned in Dr. Latham's essay, 'the whole force of the treatment was directed to the head, from a belief that the brain was inflamed. Upon dissection, the brain and its coverings were found in a perfectly healthy and natural state; and the pericardium, towards which during life there was no symptom to direct the slightest suspicion of disease, discovered the unequivocal marks of recent and acute inflammation.' Dr. Davis also, in reference to a case published by him so early as 1808, has the following remark:—"The restlessness in the case of Miss H. C. was also attended with delirium, a symptom not previously noticed as belonging to pericarditis by any writer whom I have consulted. It was so prominent a feature of the disease under which this young lady laboured, as to divert the attention of her medical attendants from its actual seat."

"This occurrence, in the course of rheumatic carditis, of cerebral symptoms calculated to perplex and obscure the true nature of the disease, is probably not so rare as has been supposed. In less than three years three instances of it have fallen under my own notice; and I have been informed by a medical man residing in the neighbourhood, that a friend of his, who has a very large general practice among the middle and lower classes, attended within the last year or two not less than twenty cases of acute rheumatism, in which a metastasis, or an extension, of the inflammation appeared to take place to the brain.

"In all the detailed cases of this kind that I have met with, and in those which I have myself watched, there were certain general points of similarity which you will do well to bear in mind. In all of them the pulse was extremely rapid; the delirium, though violent and active at intervals, was characterized for the most part by a singular, and, as it seemed, perverse taciturnity; even when the patient was evidently able to speak, and understood the questions that were put to him, he maintained a sullen silence. In most of these patients, also, not long before the fatal event, a brief interval of amendment took place, and encouraged some hope of recovery. In many of them various convulsive movements were observed; and in two of the cases the head symptoms, and probably the heart disease also, supervened after a *relapse* of the rheumatism of the joints."

It is a curious and instructive circumstance that rheumatic carditis is sometimes the first step in the whole disease. The cardiac symptoms do sometimes, I mean precede those of the joints; even by two or three days. For example.—A lad was brought to the hospital with acute articular rheumatism, and with unequivocal symptoms, which I need not detail, of carditis. He gave the following distinct history of his illness:—He had been on a visit into the country several days before, and there, after having felt poorly for nearly a week, with a sensation of "sinking within him," he ate largely of oysters, and drank more porter than he was accustomed to. On the same day he was seized with pain in the left side of the chest, and violent beating of the heart. The attack was probably a severe one, for he applied to a medical man, who immediately bled him. In the course of the ensuing night he began, for the first time in his life, to feel some stiffness beneath and about his knees, but he was able to walk about the next day. On the evening of the second day the joints became so painful and swollen, that he could not leave his bed, and the pain of the side and the palpitation diminished. This boy has several times since returned to the hospital with acute rheumatism, and on each occasion presented manifest indications of some permanent affection of the heart,—slight, probably, in amount, but aggravated upon every return of inflammation of the joints.

I have met with one or two other instances in which the cardiac disease appeared to have preceded the arthritic; but none so well made out as that which I have just related. In the *Edinburgh Medical and Surgical Journal* for 1816, Dr. Duncan

gives a case of "inflammation of the heart" which *began* with symptoms of *pectoral inflammation*, succeeded *the next day* by rheumatic affections of the joints. Dr. Fuller, in his excellent book on Rheumatism, states that three instances of this sort have fallen under his own observation: and he refers to several others, recorded by various writers.

One law respecting the connexion between the cardiac and the arthritic symptoms may be stated with confidence, namely, that the *younger* the patient is who suffers acute rheumatism (and I have seen it so early as the third or fourth year), the more likely will he be to have rheumatic carditis. The chance of the combination appears to diminish, after puberty, as life advances. I have known only three persons pass through acute rheumatism with an untouched heart prior to the age of puberty; and in two of these I am by no means certain that the articular disease was genuine rheumatism. In each of the two, the large joints became painful, and swelled, for a day or two only, towards the close of scarlet fever:—a circumstance not, I believe unusual. I was dreadfully apprehensive of carditis, but it did not occur.

I have observed also, that when a patient has come under my care who has had *repeated* attacks of acute rheumatism, in him I have generally found reason to believe that some organic affection of the heart was present. Probably the disposition to such repetitions of the disease, so remarkable in some individuals, may be kept up by the cardiac complication.

With respect to the period of the actual attack, and the circumstances under which the extension of the disease to the heart occurs, no fixed law has been observed. Sometimes the cardiac affection declares itself as the inflammation of the joints declines. Quite as often, however, they proceed together, and are aggravated or mitigated simultaneously. On this point my own experience nearly agrees with that of Dr. Latham, who says:—"It (the cardiac affection) is incident to all the degrees and all the stages, and all the forms (?) of acute rheumatism. It is not more to be looked for when the disease is severe than when it is mild; more at its beginning than during its progress and decline; more when it is shifting and inconstant in its seat, than when it is fixed and abiding."

There are some other symptoms that I must not omit to mention as occurring in some cases of pericarditis. In one of the fatal instances which fell under my own notice, there was a very strong purring tremor felt by the hand placed upon the region of the heart. This is not a constant, nor even a frequent, symptom; but it has a certain degree of corroborative value when it does occur.

When the fluid products of the inflammation predominate, when there is much serum poured out, the symptoms, as well as the danger, will be different from those which are remarked when there is not so much serous liquid. If the pericardium be distended, percussion will furnish a dull sound over an unusually large space; much beyond the natural limits of the præcordial region: and you may often measure the amount of the effusion, and its daily increase or decrease, very accurately in this manner. But the general symptoms will vary also. The pulse will be feebler, and more disposed to falter, and to become irregular, in proportion as the liquid effusion is large; and at the same time the patient will frequently be fixed in one position, and unwilling or afraid to change it, lest that small exertion should further excite the action of his heart, and hurry his respiration. He will lie, perhaps, always upon one side; or he will remain immovable on his back, with his head elevated; or he will sit up continually, with his body leaning forwards; and he will not dare to alter his posture. But when the solid products of the inflammation predominate; when there is coagulable lymph, and but little serum; when the pericardium, instead of being distended, becomes attached to the heart; then the pulse will retain that force and regularity with which the disease commenced, the dull sound yielded to percussion will not transgress the præcordial limits, and the patient will not in general experience any absolute necessity of accommodating his body to one constrained position.

Of a merely adherent pericardium there are no diagnostic signs to which, so far as I know, we can trust, either auscultatory or general. None, I mean, presented by the body at the time. If we are accurately acquainted indeed with the history of the patient's disease, and if we know that, at any time, a *to and fro* sound existed, which *to and fro* sound soon ceased, and has never recurred; then our conclusion that the pericardium is adherent will scarcely be open to any source of fallacy.

When the opposite surfaces of the membrane have been once united, they never separate again; the adhesion remains for life. But the lymph interposed between them, if the inflammation be not renewed, becomes less and less thick; until at length, in some cases, a mere layer of firm, but thin, areolar tissue is left, through which the heart is visible.

But when inflammation has stiffened the valves of the heart, or studded them with little wart-like masses of fibrin, or rendered the lining membrane of its chamber thick and opaque, how far do these morbid states admit of perfect recovery? It is not so easy to say. I am not aware of any facts which would forbid altogether the hope that here, as in iritis, the re-absorption or removal of the lymph may be total, and the restoration of the parts complete. On the contrary, the comparative infrequency of wart-like excrescences in the slowly fatal cases of rheumatic carditis leads to the opinion that such deposits may disappear as readily and entirely from the valves of the heart as from the iris: and the success of remedial measures directed against recent hypertrophy, dependent apparently upon chronic or subacute inflammation of the endocardium, is corroborative of this opinion.

One perilous way in which these vegetations may sometimes be removed I briefly adverted to when speaking of apoplexy and palsy. Portions of them, large or minute, may separate from the subjacent membrane, or be detached and washed away by the current of the blood. And serious, and even quickly fatal consequences, may result from this accident (as it may be called) of endocardial disease. A fragment of fibrin, thus carried along in the circulating blood, may stick in some blood-vessel which is too small to permit its further progress. If one of the cerebral arteries happen to be thus suddenly plugged, that portion of the brain to which its branches are distributed is deprived of much, or all, of its nutrient blood; white softening ensues, and consequent palsy. Dr. Kirkes, to whose sagacity we are indebted for almost all that we know on this interesting subject, has detailed, in the 35th volume of the *Medico-Chirurgical Transactions*, some well marked examples of this disaster. Analogous evils may follow the blocking up of a considerable artery in other parts of the body. I will mention one instance that I have lately seen. A sickly girl in her fifteenth year was attacked with acute articular rheumatism about Christmas-time, in the year 1854. She was attended by Mr. William Squire, who carefully and constantly examined the condition of her heart. No evidence of its implication occurred for the first ten days of the disease. Then began a mitral murmur, and with it signs of pulmonary congestion. Five or six days after this, an aortic murmur also became audible; and nearly at the same time her right leg, from the hip downwards, turned suddenly cold, without any loss of power, or of sensibility; and it was found that all pulsation had ceased in the right external iliac artery and its branches. She spoke of slight pain in the inguinal region on that side. Presently vesicles, containing a dark fluid, formed upon the great toe, and upon the third toe, of the right foot. Fear naturally arose that the whole leg would mortify; and the girl's life was despaired of. By great care, however, by lapping the limb in wool, and by supporting her strength, she was carried safely through that cold winter. By degrees the temperature of the leg and thigh were nearly restored; but no pulsation could be felt in the larger arteries when I saw her with Mr. Squire in October, 1855. A rough mitral bruit was then very plainly to be heard both in front and at the back of the chest; and also a less distinct aortic bellows-sound. The girl died in the following May. Unfortunately permission to examine the limb could not be obtained: but I cannot doubt that its main artery had been sealed up by solid matter, derived from one of the cardiac valves.

Minuter portions of fibrin thus detached from the lining membrane of the left side of the heart, may pass unchecked through the arteries, yet be entangled and stopped in the capillary vessels, and lead to permanent changes in the affected textures. It is in this way that many of the yellowish or buff-coloured masses of fibrin, which are familiar to morbid anatomists as being of frequent occurrence in the spleen, and in the kidneys, are supposed by Dr. Kirkes to originate.

After a similar manner branches of the pulmonary artery, or parts of the pulmonary capillary system, may be obstructed by portions of fibrin proceeding from the *right* chambers of the heart. The primary effects of these dislodgements of fibrin from the interior of the heart are mechanical: but it is very conceivable that the whole mass

of the blood may in certain cases be contaminated by the admixture of some of the fluid products of endocardial inflammation.

Since I lectured upon this subject last year, two examples of rheumatic carditis have occurred among my hospital patients, differing in some remarkable points from any that I had ever seen. A brief description of them will complete my personal experience of this terrible disease.

The histories of the two cases are curiously similar. The patients were young women; their ages respectively twenty-one and twenty-two. They were admitted during the same week: one a day after the other. Both were suffering under a first attack of rheumatic fever: both had also acute pleurisy, with effusion into the chest; and both died; one of them three weeks, the other a month, after her admission. In both cases there were symptoms referable to the heart: pain, and unnatural sounds; but in neither case was there any friction-sound; nor were any traces of pericarditis discovered after death. But the inflammation had fallen, partially, upon the aortic valves; whence it had extended (so I imagine) to the muscular substance. I show you the morbid appearances represented in these drawings, made by Mr. Lonsdale at the time: and, better still, I show you the parts themselves, which are preserved in our museum.

The whole of one cusp of the aortic valves was, in each case, a mass of ragged ulceration; and the adjacent portions of the two other cusps were, in a slighter degree, implicated in the mischief. What remained of the tattered valve was covered with rough irregular shreds of lymph, or vegetations. In one of the cases, the ulcerating process had penetrated through the valve, and into the muscular substance beyond, and had eaten a hole completely through the septum. A portion of lymph protruded just below the valves of the pulmonary artery through the channel of communication thus formed between the left and right sides of the heart. In the other case, an abscess as large as a hazel-nut was found in the muscular substance of the septum, immediately opposite the disorganized valve.

Till I met with these cases I was not aware that this destructive incrustation of the cardiac valves with wart-like excrescences was ever the result of *acute* inflammation. Chronic changes of that kind are not uncommon. Suppuration in the heart is very rare. With such mischief in rapid progress within the heart, it is easy to see how the blood may be polluted, and charged with a new poison in its very fountain. In these two instances, the cardiac affection was complicated with acute pleurisy. I should have mentioned before, that the pleura very often participates in the inflammation when pericarditis occurs. You will not wonder at this if you consider the close vicinity, and the similarity in texture, of these two serous membranes. Nor will you be surprised when I add, that the pleurisy is often associated with pneumonia also. Upon these accessory disorders the immediate danger of the case not unfrequently hinges.

With respect to the comparative frequency of these various complications of acute rheumatism, I may state briefly the result of Dr. Latham's computed experience, which is in general accordance with my own. Of those who suffer acute articular rheumatism, not less than two-thirds suffer also some form of cardiac inflammation. Of these forms, endocarditis is the least formidable, and much the most common: occurring nine times as frequently as pericarditis. Again, it is with the rarer, and at the same time the most perilous form of cardiac inflammation — with pericarditis, or with pericarditis and endocarditis combined — that pulmonary inflammation (including bronchitis, pleuritis, and pneumonia) is most apt to be associated.

I must defer what I have to say respecting the treatment of acute pericarditis and endocarditis, to the next lecture.

LECTURE LXII.

Treatment of acute Pericarditis, and Endocarditis: blood-letting; mercury; blisters. Chronic and partial inflammation of the Pericardium. Disease of the Aorta. Thoracic Aneurisms; their various situations, and symptoms: plan of treatment.

I TRUST that I made distinctly apparent in the last lecture, the great danger which belongs to every case of acute inflammation of the pericardium. First, there is the danger of *speedy death*. If the inflammation go to the extent of effusion, and the collection of serous fluid be large, and the pericardium be distended by it, the action of the heart is so much oppressed by the liquid surrounding it, that it falters and flutters, and at length stops, and goes on no more. Secondly, there is the danger that (the pericardium having become adherent) other structural changes may soon, or slowly, develop themselves; and first render life burdensome and full of suffering; and then consign the patient to an earlier grave than might else have awaited him. Again, if the endocardium alone be affected, there is the danger of such permanent valvular damage as may obstruct the onward current of the blood, or destroy the natural and necessary bar to its reflux: and therefore the danger of gradual hypertrophy and dilatation, with all their distressing consequences. There is also the further risk, that the seeds of disease may be conveyed to other organs of the body, from the interior of the heart, with the circulating blood. When both the lining and the investing membrane of the heart are involved in the morbid process, the hazard is obviously doubled.

Now what can we do to prevent, or to diminish, these evils? I once thought that if we caught the inflammation at its very commencement, we might calculate upon a perfect cure, by first bleeding the patient freely, and by, secondly, putting him as speedily as possible under the specific influence of mercury. I am sorry to be obliged to say, that the more I see of this formidable malady, the more reason I find for fearing that it is seldom within the possibility of thorough repair. Bring the inflammation to a stop, you perhaps may; or nature will do it for you; and you may greatly assist the natural powers in effecting this. But that alone can be called a cure, which either leaves the structure of the part affected in its original integrity; or, at any rate, leaves no spring or source of further changes for the worse: and such complete recovery as this I seldom dare to hope for, in cases of acute and general carditis.

There can be no use in deceiving ourselves in this matter; but we may very easily deceive ourselves. In a large proportion of cases, whether they be treated well, or ill, or not treated at all, the patients will *seem* to recover. But I say that the recovery is so far unreal, that it involves the germ of future destruction. If any of you have read Bouillaud's heavy, yet instructive, work on diseases of the heart, you will know that he boasts of the success of his treatment in acute pericarditis. He declares that by the bold use of the lancet he *extinguishes* the inflammation; jugulates (as he calls it) or slaughters the disease at its birth; and restores the patient to the full condition of health, or to the state in which he was before the disease came on. You must hereafter judge of this question for yourselves; but it is my duty to caution you against crediting these statements. Not that I would insinuate a doubt of M. Bouillaud's veracity; but I believe that he has been deceived by false recoveries; and I would not have you beguiled, by his representations, into the indiscriminate adoption of that "enlightened hardness" which he endeavours to inculcate.

But if we look closely at his statements, we do not find, after all, any such wonderful success. Of 18 patients, 6 died: a very large proportion, 1, viz. in 3. To be sure, with some ingenuity he makes the proportion to be 1 in 7. For three of the fatal cases occurred, he says, before he took to his heroic plan of blood-letting; and excluding these 3, he has 15 cases, and only 3 deaths; or 1 in 5. But one of these three proved fatal from the supervention of tetanus; therefore setting that also aside, there will be 14 cases of the disease and two deaths. Now, I have not, hitherto, been able to look through my case-books in reference to this point, but I am quite

certain that the mortality in the Middlesex Hospital has been nothing like so great as that — the *immediate* mortality, of course, I mean — either among my patients, or among those of my colleagues; and I know that, until within the last twelve months, Dr. Latham had not lost a single case of rheumatic pericarditis in the course of the first attack of that disease for several preceding years.

But what I most doubt about, is the *true* recovery of Bouillaud's surviving patients. I say such patients do *apparently* get well. In some of them, indeed, a bellows-sound remains, sufficiently indicative of the damage that the organ has sustained: and I have already told you that *any* amount of change, however small, which alters the healthy proportion between the cavities and their outlets, or which interferes with the natural play of the heart, is a seed from which further changes will at length be found to grow. But patients will get so far well that you can detect nothing wrong about them. Follow them, however, in their subsequent lives; and you will learn that many of them very soon begin to find that they are incapable of doing or enduring all that they could do or endure before their illness: and if this do not soon happen, it happens at last. The disease of the heart (if the patient be not cut off by some other malady) becomes at length obvious: and when he dies, the source of the ultimate changes is commonly to be detected. There is adhesion of the pericardium; or there is disease of the valves; of which no other account can be given than that these had continued to exist since the primary symptoms of carditis ceased; and had caused all the rest — the hypertrophy, to wit, the dilatation, or the wasting.

The remarks that I have now been making bear upon the question, to what amount blood-letting should be carried in acute pericarditis. If the general symptoms teach you that it exists, and yet no sound of attrition is heard, you may, in that case, if in any, hope to arrest the inflammation, and to achieve a complete cure, by the early abstraction of blood. But if the *to and fro* sound have been audible, I do not think the consequences of the inflammation can be so abolished. I believe that the best event which can then happen is adhesion. We must, however, in many cases, take blood either by the lancet from the arm, or by leeches from the præcordial region; yet not in the lavish manner recommended by Bouillaud. I know that his treatment has been fairly tried in this country, and has failed. And I think (but this I only offer as an opinion) that there is a peculiar risk in frequently bleeding to syncope in this affection. There is, almost always, endocarditis (in the rheumatic cases at least) coincident with the pericarditis: and there is a readiness or tendency towards a deposit of the fibrin of the blood, in the shape of minute vegetations, upon the inflamed valves: and it is probable that this tendency may be favoured by a retarded movement of the blood over them; and still more so by its temporary stagnation. In the experiments on the ass, referred to before, the circulation (kept up by artificial breathing) became languid and sluggish, and vegetations were deposited upon those valves which had been irritated by the wire. Hence there is, I think, a danger in bleeding to such an extent in these cases, as to bring the heart's action to a pause *in deliquium*. Bleed, therefore (if you deem it requisite to bleed at all), till some effect upon the pulse has been accomplished, and then stop: and renew the venæsection, or refrain from it, according to circumstances. But you may freely cup the præcordial region, or cover it repeatedly with leeches: and to this mode of abstracting blood, from the neighbourhood of the inflamed part, my own experience would assign the preference. In fact, I seldom open a vein in such cases.

At the same time, you will endeavour to get the gums tender with mercury. And it is most unfortunate that, in this disease, the system frequently resists, with great obstinacy, the influence of that mineral. Sometimes, do what you will, you fail to attain your object. A knowledge of this fact may render you less scrupulous than you would otherwise be in the use of the remedy. Not only should calomel be given in frequently repeated doses, guarded, if need be, by opium, but mercurial inunction should also be had recourse to, in these perilous cases, from the first. When the gums do begin to rise, there is always, according to my experience, a manifest subsidence of the distress, and mitigation of the symptoms: less pain, less palpitation, less dyspnoea. The mouth should be *kept* sore for some time together: for supposing the membranes to adhere, it does not follow that the inflammatory process should thereupon cease.

When you learn, from symptoms and signs already described, that the pericardium

is distended by liquid effusion, I would advise you to lay a large blister over the præcordia. The diminution, or complete disappearance of the liquid, under this treatment, is often rapid and striking.

Even when all the symptoms have departed, previous disappointments have taught me not to be sanguine as to the permanency of the recovery. I believe that months, and years even, may elapse before the secondary effects of the mischief left behind by the inflammation begin to be palpable. But in many instances they show themselves very early. Others have noticed all this; especially Dr. Latham, who truly remarks, that “in acute pericarditis there is no medium between complete cure and certain death.” He deemed, at the time when the lectures from which I quote were given, that the early and vigorous use of mercury might be equal to the complete cure. But in his more recent work, *On Diseases of the Heart*,—in which the whole of this subject is most instructively treated in detail, and which I cannot too strongly commend to your diligent study—I find, with a melancholy sort of satisfaction, that his final belief is in no respect different from my own. I have several times already expressed my conviction, that when the *to and fro* sound has manifested itself, that is, when the inflammation has gone so far as the effusion of coagulable lymph, if the patient do not die outright, he survives at the expense of an adherent pericardium; and he survives only for a time. *Hæret lateri lethalis arundo*. But I am also of opinion, that by the cautious employment of the lancet and of leeches, and by the early and unshrinking use of mercury, the mischief may be greatly limited, and the consecutive changes staved off to a distant period. The final catastrophe arrives much more slowly, and in a somewhat different way, when there is mere adhesion of the pericardium, than when that condition is complicated with permanent disease of the valves within the heart, or of the lining membrane of the ventricles. The complete cure of pericarditis is less within the scope of well-directed remedies, than the complete cure of endocarditis. On the other hand, abiding changes of the endocardium are more surely and more rapidly fatal, by impeding the current of the blood, and so inducing hypertrophy and dilatation, than abiding adhesion of the pericardium. Dr. Munk’s observations suggest the belief that in some of those cases in which the secondary effects of rheumatic carditis become early visible, the endocardial inflammation has insidiously lingered on, after the articular disease had vanished. What seems but a slow convalescence, is really incipient disorganization of the heart. The evidence of such persisting endocarditis must therefore be carefully and continually looked for; and its appropriate remedy, which is mercury, must be as diligently plied and adjusted. The inflammation remaining unchecked, simple hypertrophy will probably ensue when the membrane covering the walls of the ventricle is alone affected—hypertrophy with dilatation when the valves are implicated. I need scarcely say that other, minor expedients, are also to be put in force; strict abstinence I mean, perfect quiet, and an occasional purgative to clear out the alimentary canal.

When the pericardium has once become adherent, if (as is very likely) the patient again suffers acute rheumatism, he may again have heart symptoms. Not of course, the *to and fro* sound; but pain, palpitation, and dyspnoea. Now it is of some practical importance to be aware that this renewal of morbid action does not require that active treatment which the primary inflammation demanded. The effect of such renewal will be to augment the existing mischief; but the morbid process is much less vigorous, and much more easily subdued. It will generally yield to the repeated application of a few leeches, or of blisters, over the situation of the heart, and to the moderate exhibition of mercury.

Although acute inflammation in this, as in other serous membranes, shows generally a strong disposition to spread all over the affected surface; yet does the pericardium seem readily susceptible of slight and partial inflammation. You will very frequently indeed see, upon laying the bag open, a white spot, as big as the finger-nail, upon the surface of the heart. I have examined these spots very often; and I believe they almost always consist of a thin flake of lymph lying sometimes beneath, but oftener upon, the membrane. They may, in fact, be peeled off sometimes, and the subjacent membrane be left smooth and sound. On one occasion, I met with a long riband of lymph passing from the centre of one of these white spots, to connect itself with the loose bag of the pericardium. I conclude, therefore, that these spots are really the result of a very limited inflammatory process: but under what condi-

tions they arise, or whether during their formation they furnish any symptoms, I do not know.

Such is the view which I had long taken, and taught, of these white spots upon the surface of the heart; and I am glad to have it confirmed by the observation of Mr. Paget, who has adduced (in the twenty-third volume of the *Medico-Chirurgical Transactions*) conclusive evidence, both of their frequency, and of their inflammatory origin.

You may ask me whether inflammation of the pericardium, even when it is slight and partial,—such as might account for these spots—can ever take place without giving rise to a friction sound. It is highly probable that it cannot. Yet, as such inflammation is attended with no febrile disturbance or general distress, and probably with no severe or abiding pain, or no pain at all, it is not brought under the scrutiny of the physician, and may be scarcely noticed by the patient himself. So that the friction sounds are not heard, because they are not hearkened for. In this respect the formation of the white spots on the heart has some analogy with the formation of those pulmonary adhesions, which are such common results of dry and partial pleurisies.

I have spoken of acute pericarditis as it presents itself in frequent association with articular rheumatism; and I have shown you how fearfully serious a character is imparted by that complication to a disorder which, however painful, is otherwise devoid of danger. The same complication arises sometimes during the progress of the febrile exanthemata, and especially of scarlet fever. In both cases there is a blood-poison at work: in both cases the course, the clinical history, the gravity, and the appropriate treatment of the supervening disease, are essentially the same. And the patients are of the same class, being mostly young, or not old, and of previously sound health.

But inflammation of the pericardium is far from being uncommon under very different circumstances; in persons advanced in life, and with constitutions broken by previous disease. We trace it, often unexpectedly, in its effects—in the presence of lymph recently effused, and smeared over the surfaces of the membrane—after death by various chronic maladies, and above all, after death from that renal malady which has given to the name of Bright an immortality of reputation. In that disease also the blood may well be said to contain a poison. The frequency of this insidious form of pericarditis at the close of other diseases was fairly brought to light by the laborious and accurate researches of the late Dr. John Taylor. Its comparative lack of interest has been well weighed and set forth by Dr. Ormerod. The importance of the pericardial inflammation in these cases is practically but little. Dr. Ormerod truly observes of it, that it falls more within the province of the morbid anatomist than of the physician. Its symptoms are so slightly and uncertainly marked, that the fact of the inflammation is often recognised only in the corpse. It accompanies, rather than causes, death. It does not destroy life, but takes place because the patient is already dying. Other serous surfaces are apt to suffer inflammation under precisely similar circumstances. This kind of pericarditis scarcely submits itself to treatment. It is proper that you should be aware of its frequency, and of its nature: but it requires no further consideration in these lectures.

So much then for the heart itself, and its membranes. There still remain to be considered the morbid conditions of the great vessels that spring from it, and lie in the thorax, and especially of the aorta; those morbid conditions, I mean, which declare themselves by symptoms, and which become the object of medical treatment.

The aorta is very frequently indeed found diseased; and its disease, as I have already explained, is a common cause of organic changes in the left ventricle of the heart. You will find that its interior surface, instead of being smooth, and of a uniform yellowish white colour, is rendered very uneven by a great number of yellow opaque projections, of cartilaginous consistence, lying immediately beneath the membrane. And in a more advanced stage of the same diseased condition, you may perceive that some of these projecting little masses consist of irregular scales of bone, having sharp edges; and sometimes these plates of ossific matter are quite bare; the inner membrane is gone, and the exposed bone is washed by the current of blood.

Now the necessary effect of these changes is to diminish and destroy the natural elasticity of the vessel; and as there is a perpetually recurring strain upon it, by the blood sent out from the heart, the vessel dilates, becomes larger than it should be. This, if you please, you may call aneurism; but a simpler name is dilatation. In other cases, the enlargement is not general, but partial. A pouch is formed on one side of the artery, and this pouch may be very small or very large. It appears to result from the giving way, the rupture in short, or the ulceration, of the inner and middle coats of the artery, and then the blood, passing through the broken part, presses against the cellular coat of the vessel, and distends it into a sort of bag. There have been curious discussions as to what should be called true aneurism; and what should be called false aneurism; discussions upon which I have neither time nor taste for entering. It is enough for all practical purposes to state, that the artery sometimes dilates only, sometimes throws out a pouch. I know that you have received, or will receive, from my colleague Mr. Arnott, all the information that is requisite concerning the modes in which aneurism may arise. These are matters of the highest interest in surgery, for surgery can cure an aneurism; an achievement which is but seldom within the skill of physic.

I have known three or four cases in which the diseased artery all at once cracked across—its inner and middle coats, I mean—and death very rapidly ensued. In one of these instances, the crack extended round a considerable part of the circumference of the aorta. It looked exactly like a clean cut made by a sharp knife. The blood, in this example, dissected its way (if I may so say) between the middle and external coats of the aorta, and got at last into the pericardium, and coagulated round the heart in a uniform layer: so that a *bag* of coagulated blood was enclosed in the bag of the pericardium. In another case, which I mentioned in a former lecture, the dissecting blood shut up the right carotid artery, and fatal hemiplegia from white softening of the brain was the result. Of course, nothing can be done for such cases as these.

Most commonly the aneurismal tumour goes on enlarging: and often it becomes lined, and sometimes it is nearly filled up, by layers of coagulated blood, which form in its interior. At length the tumour bursts, and the patient perishes.

Fig. 87.

Fig. 88.

Fig. 87.—Section of the arch of an aorta, with an aneurism arising from its upper part. The cavity of the sac is nearly filled by laminated coagulum, the internal membrane of the artery is thickened. The sac presses against the trachea, the arteria innominata, and the right carotid and subclavian arteries.—St. Bartholomew's Museum, Series xiii. No. 11.

Fig. 88.—Further growth of aneurism prevented by coagulum becoming adherent to the artery around the opening of the sac.—From Hodgson.

Aneurisms of the thoracic aorta are met with chiefly in the earlier portions of that vessel, in its ascending part, and in its arch. There seem to be two reasons for this. One is, that the diseased state of the coats of the artery (to which the rupture and subsequent aneurismal pouch, or the dilatation, as the case may be, are owing) is more common, and more advanced generally in that part of the aorta; and another reason is, that the momentum of the blood, as it is forcibly propelled from the left ventricle, is sustained chiefly by the same part.

Mere disease or dilatation of the commencing aorta affords, as I formerly endeavoured to explain, a physical impediment to the due emptying of the left ventricle. It is a common cause, therefore, of hypertrophy and dilatation of that ventricle; and consequently, the *signs* of hypertrophy and dilatation of the left ventricle of the heart will at length result from disease and enlargement of the aorta near its mouth.

When aneurismal pouches form, as they often do, at the very entrance of the aorta, or in the coronary arteries, they often defy detection. I, at least, know of no sign of their existence upon which a physician can rely, or which can lead him even to suspect such a state of matters. But all at once the patient drops down dead: and upon searching for the cause of this sudden extinction of life, you find the pericardium distended with blood, and the source of that blood you find to be the ruptured aneurismal pouch, so near the root of the aorta, as to project *within the pericardium*. In the preparation which I hold in my hand, an unbroken aneurism actually bulges into the *right ventricle* of the heart.

When the aneurismal tumour occupies a portion of the ascending aorta a little more distant from the heart, or is formed at the arch itself, it sometimes attains a large size, and the evidence of its presence is derived from the effects its enlargement produces on the surrounding textures; and these effects are apt, for a while, to be obscure and equivocal, until an external pulsating swelling makes its appearance, or a sudden gush of arterial blood through the mouth discloses the true nature of the malady.

In these cases we *infer* the existence of aneurism sometimes from peculiar symptoms. Aneurism at the arch of the aorta may come to press upon the trachea, and impede the breathing; or by its effect upon the recurrent nerves, it may cause a very accurate mimicry of laryngitis; producing raucous voice and stridulous inspiration. The operation of tracheotomy, as I told you before, has more than once been performed, to relieve the supposed inflamed condition of the larynx, while the sole disease was aneurism at the arch of the aorta. Such mistakes are always discreditable; and the lesson they furnish should not be lost upon us. Whenever we find that a wheezing dyspnoea has gradually arisen, which no apparent affection of the air-passages satisfactorily accounts for, and the patient has a sense of pulsation within the thorax, we may suspect that an aneurism is at the bottom of these symptoms.

The effect of aneurismal enlargements of the artery in causing *absorption* of the neighbouring tissues, upon which the tumour presses, is very curious. You know that even the solid bone is removed, worn away as it were, before an advancing aneurism. Hence it not unfrequently happens that the trachea, or some of the larger bronchi, are at first flattened, and then give way; the aneurism breaks into the air-passages; and the patient, overwhelmed by a torrent of blood into and from his lungs, perishes in a few seconds. Or the tumour may contract adhesions with the pulmonary tissue, and destroy it to a certain extent, and *so* cause mortal hæmoptysis. But such cases are not always *fatal at once*. Not unfrequently the blood bursts into the sac of one or of the other pleura.

Again, according to its situation and extent, an aneurism of the thoracic aorta may press upon the œsophagus, and cause the ordinary symptoms of stricture of that tube. Hence cardiac disease, and pulsation within the chest, accompanied at length by the signs of a constricted œsophagus, form strong presumptive indications of the existence of an aneurism; and in such cases, the œsophagus may at last ulcerate through, and then copious and fatal hæmorrhage ensues. Hæmatemesis it may be called, though the blood is vomited not from the stomach, but from the gullet. A patient in the Middlesex Hospital, with symptoms of stricture of the œsophagus, one day brought up from the throat a red mass, which, at the moment, was supposed to be a bit of meat that he had been trying to swallow. It really was part of the clot from an aneurism; and it was speedily followed by a stream of red blood, and by death.

Again, aneurism of the thoracic aorta does frequently obstruct, by its juxta-position and pressure, the vena cava superior; nay, it may even obliterate that vessel, of which

Fig. 89.

Fig. 90.

Fig. 89 exhibits a front, and Fig. 90 a back view of an aneurism of the arch of the aorta, which burst into the trachea. The opening into the aneurism from the artery, and the atheromatous patches between the coats of the latter, are well shown.

I have seen two instances. To one of these cases I alluded before, as a most curious example of dropsy. It illustrated exceedingly well the effect of venous obstruction in causing serous effusion. The man was a patient of Dr. Hawkins'. He presented a most extraordinary spectacle. His face, neck and arms were tumid and anasarctous to an enormous degree; while there was not the least trace of swelling or œdema anywhere below the ribs. He looked as if his upper half had been stuffed; and except that it was distressing, his appearance was extremely comical. His countenance was livid; his eyes seemed starting from their sockets; and even the areolar tissue beneath the conjunctiva was œdematous. The integuments of his neck and chest were quite brawny; and his arms were so swollen that they projected from his sides. The surface of the thorax in front was embossed by numerous veins, which were turgid with blood; and here and there patches of ecchymosis were visible. You may form some notion of the degree of mechanical congestion that existed, when I tell you that, upon the scarificator being applied, after a cupping-glass was taken off, upwards of twenty ounces of blood escaped in two minutes. The epigastric veins were visible and tortuous, and a free communication by anastomosis existed between these veins ascending from the inguinal region, and the mammary veins. There was a bellows-sound, which increased in loudness and harshness, from the root of the aorta to the top of the sternum. The patient soon died; and a large aneurism of the aorta was laid open by lifting up the sternum, to which the artery had adhered, and into which, indeed, it had eaten a little. Not far above the right auricle, the vena cava was totally impervious; its sides having been gradually pressed together, as the tumour grew. The other case, of the same kind, which occurred in one of my own patients, I shall have occasion to refer to hereafter.

But aneurism of the thoracic aorta, and especially aneurism of its descending portion, may exercise its pressure in another quarter, and wear away the bones of the vertebræ, and cause pain in the back, radiating often in the direction of the intercostal nerves, and ultimately palsy perhaps of the parts below that portion of the spinal cord; so that pain in the back, with pulsation, may justly awaken suspicion of aneurism making its way backwards. I remember hearing Dr. Farre describe a case of this kind, to inculcate the necessity of paying attention to the *sensations* of a patient. A man came to him for advice, having been told by another physician that there was nothing the matter with him—that he was fanciful. But when an adult person makes constant complaint of certain morbid feelings in a part, the probability is that he *has* something the matter, and we must investigate the case with what helps we can get. In the instance in question, there were two signs of disease, and two only; a white

tongue, and pain in the back. The whiteness of the tongue soon disappeared under the use of some medicine addressed to the digestive organs. The pain in the back remained. Dr. Farre interrogated his patient minutely every time he visited him, till at last the man got vexed and tired, and said pettishly, "I know that if you split me down the middle, I am sound on my right side, and diseased on my left." Very soon after, he was found dead in his bed. What he had said was perfectly true: there was an aneurism pressing on the left side of the dorsal vertebræ.

Another consequence of an enlarging thoracic aneurism, sometimes observed, is pressure upon the *thoracic duct*, causing engorgement of the absorbent vessels and glands, and inanition. In short, whatever parts the aneurism may reach, and subject to its pressure, may have their function thereby suspended or disturbed, or their structure spoiled.

One sign, which I have myself frequently verified, of aneurism of the arch of the aorta, is a difference in the force of the pulse in the two radial arteries. The pulse in the one wrist (more commonly the left) will be extremely feeble, or even disappear. This happens when the state and position of the *arteria innominata*, or of the left subclavian artery, become altered in consequence of the enlargement of the aorta; and sometimes the one or the other of these arteries is completely closed up. But inasmuch as a similar difference of the pulses may arise from other causes, we can only look upon this symptom as one which may help to solve an ambiguous case. To give you an example of a difference in the beating of the arteries in the two wrists from other causes, I may mention a case in which the subclavian

Fig. 91.

Aneurism of the aorta, which induced caries of the vertebræ, and fatal compression of the spinal cord.

Fig. 92.

Fig. 92.—Front view of aneurism of aorta.

Fig. 93.

Fig. 93.—Back view of same preparation, showing the aneurism, producing absorption of the ribs, and making its way to the surface. Death was caused by part of the coagulum falling into the artery.

pressed, by an exostosis on the first rib. The case is mentioned in Mr. Mayo's Pathology. It occurred in a patient of mine, the husband of a nurse in my family.

I had a girl for some time in the hospital, in one of whose arms no artery could be found to pulsate. Why, we none of us could make out.

Some time ago, a surgeon from the country came to my house, desirous (he said) to consult me about a sense of discomfort in his head; and particularly about the state of his vision. When erect, he saw things obscurely. At three yards' distance he could see my face, but could not distinguish the separate features. What he thought very strange was that he could see perfectly well when in the horizontal posture.

On my proceeding to feel his pulse, he said, in a careless manner, "By-the-by, that is another thing wrong with me; I have no pulse." Nor could I detect any, in either arm. He then told me that, four or five years previously, a medical friend, intending to feel his pulse in the left wrist, could find none. He was confident that pulsation had existed a short time before. After a while, the movement of the radial artery returned, in a very slight degree; and then finally ceased. Within nine or ten months of this discovery, the right pulse, after growing less and less distinct by degrees, had vanished also. Though somewhat weak, and subject to faintness, this gentleman had not wasted; nor had the muscles of his arms lost either bulk or vigour. Their veins were full enough of blood. His hands were often cold; and he felt altogether worse during cold weather.

Failing to detect any pulsation in the brachial and subclavian arteries, I next felt for the carotids: but I could perceive no beating in the track of their course. I had placed my finger, for a few seconds only, in front of the left sterno-mastoid muscle—when I saw that his head drooped, his cheeks became white, and he was on the brink of fainting. But he recovered immediately. Then I made similar pressure, for a moment, on the right side of the neck, and the same phenomena were instantly repeated, with the addition of convulsive jerking movements of the head and arms. He rallied again directly upon my removing my finger, and was scarcely aware of what had happened. For a second or two he had been unconscious. His femoral arteries throbbed as usual.

I next examined his chest. There was no external irregularity or want of symmetry. Percussion gave a clear resonant sound everywhere in front. The heart was heard, beating with frequency, but without any bruit, over the greater part of the thorax. Its impulse in the præcordial region, below the nipple, was feeble: but a strong jarring impulse was communicated to the ear when the stethoscope was applied to the upper part of the sternum.

The patient complained of pains affecting his shoulders, clavicles, and the back of his neck; and of slight difficulty of swallowing.

From the intelligent physician who had attended this gentleman in the country, I learned the instructive fact that, twenty months before, a loud rasping bruit had been audible, without impulse, at that part of the sternum where he, as well as I, now found no bruit at all, and a very considerable impulse.

I could not doubt that in this painfully interesting case there was aneurismal disease of the aorta, interfering with and lessening, but not absolutely excluding, the stream of blood through the arteries which spring from its arch.

The patient continued to live on, incapable, however, of any exertion, for upwards of two years; when one evening, upon his raising himself from the sofa to cough, arterial blood suddenly poured from his mouth and nostrils, and he was presently dead. I am indebted to Dr. Durrant, of Ipswich, for an account of the morbid appearances discovered upon opening his thorax.

The ribs and sternum being raised, the aorta was seen enlarged, slightly projecting forwards, and overlapped by the lung. When the lungs had been removed, the whole arch became visible, enormously dilated, firm, inelastic, and adherent to the bodies of the second, third, and fourth dorsal vertebræ. More than two-thirds of the interior of the dilated vessel was filled up with dense fibrin, looking like muscle. The lining membrane of the aneurismal part was ossified throughout; the earthy matter lying in separate pieces, many of which resembled concave shells. The bodies of the third and fourth vertebræ, and the left half of the body of the second, were absorbed, the intervening cartilages remaining entire. The vertebral canal was bounded, in part, by the posterior wall of the aneurism. The *arteria inominata* was slightly dilated, the subclavian and brachial arteries were pervious, but attenuated;

their fibrous coat being softer than natural, and much less elastic. The heart was atrophied; weighing probably not more than five ounces. Both lungs were congested, and their lower borders were emphysematous. The aneurism communicated with the trachea by an aperture about as big as a quill.

It is an interesting fact, deduced by Dr. Sibson from the analysis of nearly 900 instances of aneurism, that those cases which end by rupture of the sac are attended during life with less formidable symptoms than those which kill without such rupture; and sometimes with no symptoms at all. The patient may seem, and may believe himself to be, in perfect health. The reason of this is obvious enough. Rupture is often prevented by some opposing part, upon which the enlarging tumour makes distressful pressure.

In the numerous specimens upon the table, you will find ample evidence and illustration of almost every one of the effects which I have described as apt to result from the pressure of thoracic aneurisms of the aorta. But similar effects would ensue from the same degree of pressure, however caused; and other morbid tumours, cancerous tumours in particular, are not uncommon within the thorax. Hence these same effects, considered as symptoms, are in themselves of equivocal import. If they occur in conjunction with signs of disordered circulation, or of a diseased heart, we may reasonably conjecture that they are produced by an aneurism. But we can seldom be quite sure of this, until the advancing aneurism comes near the surface, and causes an external prominence or tumour which pulsates visibly, or of which the pulsations are perceptible by the touch. And even then it may require some care and tact, to avoid mistaking an enlarged gland or a malignant growth, lying over a sound artery, and receiving an impulse from it, or communicating to it some unnatural sound, for the diseased vessel itself.

The pulsating tumour, if the aneurism have formed in the ascending aorta, makes its appearance, usually on the right side of the sternum. If the aneurism be situated in the fore-part of the arch, it produces a bulging at the sternal extremities of the upper ribs of that side. When it springs from the summit of the arch, the tumour rises above the sternum, and the sternal ends of the clavicles; and when the disease occupies the descending portion of the thoracic aorta, it will sometimes destroy the ribs and the bodies of the vertebrae, and push forward the lower portion of the left scapula: or it may show itself in front, beneath the left clavicle.

When such a tumour presents itself, and is attended with a steady, heaving pulsation, synchronous with the systole of the heart, the doubt and obscurity which may have previously hung over the nature of the patient's disorder is cleared away. A little attention to all the circumstances of the case, will generally suffice to determine its true character.

There are, however, some errors prevalent respecting these pulsating tumours, which errors I shall glance at in passing. In the first place, the pulsation of the tumour is frequently attended with a rough bellows-sound; and some persons rely upon this as distinctive of the nature of the pulsating tumour. They hold that this harsh bellows-sound is always discernible in an aneurismal tumour; and that when such a sound cannot be heard, the tumour is not aneurism. But this is a mistake. There have been in the Middlesex Hospital within the last six months (1837), two instances of pulsating tumours in the fore-part of the thorax, unattended with any bellows-sound; yet they were both ascertained, after death, to be aneurismal tumours. One of the aneurisms is before you. It results from Dr. Sibson's researches that, in reality, a bellows-sound is more often absent than present. In the case of the country surgeon, a bellows-sound was heard at a certain period of the disease, but ceased at a more advanced period. I may say the same of the purring thrill. It is a common, but by no means a necessary attendant upon thoracic aneurisms. Again, much stress was laid by Laennec, upon the circumstance of the aneurismal pulsation being single, being unattended by any second sound. But this is not a true rule if taken universally. In the instance which furnished this very preparation, the sounds were double, just like those of the heart. The second sound heard *is*, no doubt, the second sound of the heart, conveyed from the place of the aortic valves, where it originates, along the course of the vessel, to the aneurism; which often indeed lies in contact with the heart, and could scarcely fail to have the diastolic sound propagated through it. It is a fact not so easily explained, yet it certainly is a fact, that a double sound *may* be

audible in aneurisms very distant from the heart. Dr. Davies states, that he never heard a second sound in abdominal aneurisms; yet I presume that, under favourable circumstances, the sound of the closing of the floodgates at the root of the aorta, may be heard far along its channel. I can account in no other way for the second sound, heard by myself and by many others, in a *popliteal* aneurism. I mentioned before a patient whom I saw in St. Bartholomew's Hospital, and in whom an exceedingly loud diastolic sound, like the sharp whining note of a dog, was audible by the ear placed upon his arm, over the brachial, and even over the radial arteries.

There are some judicious remarks made by Dr. Hope upon the sounds that are apt to be heard in these pulsating aneurismal tumours to the right of the sternum; showing how they may be distinguished from the natural sounds of the heart itself, conveyed to that spot through some dense conducting medium. He observes (and all that I have seen has been consonant with this observation), that the first of the aneurismal sounds, when there are two, the sound that coincides with the pulse, is always louder than the natural systolic sound of the heart, and generally louder than any of the morbid systolic sounds; and that instead of increasing in intensity, as the stethoscope is moved gradually towards the præcordial region (as it ought to do, if it were the conducted sound of the heart itself), it diminishes in loudness, until it is gradually lost in the actual systole of the heart. Whereas the second sound heard over the tumour does augment as we get nearer the heart, for it is, in truth, the diastolic sound of the heart, and therefore is more audible as we approach the point where it is generated. The sounds of aneurisms of the aorta are usually audible in the back also; and if a very loud bellows-sound be heard there, where the natural sounds, if heard at all, are always much abated, that circumstance furnishes a strong additional ground for suspecting the presence of an aneurism, or of some great change in the aorta.

To give you some notion of the course which aneurism of the thoracic aorta may run, I will describe another instance of that disease which occurred under my own observation. The subject of it supplied the preparation to which I last referred.

He was a stout, healthy-looking man, forty years old, a private coachman. He became my patient in the hospital on the 8th of September, 1836. He complained of pain and tenderness around and above the right mamma. The pain was increased by a full inspiration: and when lying on the opposite side, he felt as though he was tied in the painful part.

He had been ill a month only. His illness commenced with severe rigors, and fever, and sudden pain in the side, for which he was bled three times with much relief. He attributed the attack to having lain, upon his right side, in a damp bed.

There was scarcely any projection at the spot where the pain and tenderness were experienced. By careful examination, several times repeated, I satisfied myself upon the following points.

On the right side of the thorax no vesicular breathing could be heard; and the whole was dull on percussion. On the left side percussion gave a hollow sound, and the respiratory murmur was clear and strong. In the tender spot, an inch and a half above the mamma on the right side, a strong pulsation could be felt, and two sounds were distinctly audible, the first of them keeping time with the pulse at the wrist. But there was no bellows-sound. M. Sanson, the celebrated French surgeon, was then in London, and went round with me one day, and examined this patient; and he expressed his opinion that it was not a case of aneurism, because there was no *whiz* or bellows-sound to be heard. Of course his examination was a cursory one, and I mention this circumstance merely to show you what importance has been attributed to the presence or absence of a *bruit de soufflet* in such cases. M. Sanson suggested that the heart might be displaced, and pushed over to the right side. However, it was clear to me that this could not be the case, because the breathing was deficient, not on the left, but on the right side; and, above all, because the apex of the heart could be both seen and felt beating in its proper situation, in the præcordial region on the left side. Also on the left side, percussion made on the edge of the ribs gave a tympanitic sound, indicating the place of the stomach; on the right a dull sound, pointing out the situation of the liver; so that it was not a case of transposition of the viscera, such as had been found, not long before, in one of my patients. In the course of the disease, a slight bellows-sound did become perceptible over the right mamma, when the patient sat up; but even then, the natural sounds of the heart,

without any morbid quality, could be heard in the natural position of that organ. Œgophony was audible at the back part of the right side of the chest.

This patient had repeated attacks of pain, dyspnœa, restlessness, and inability to lie down; and these attacks were always most sensibly mitigated by the application of leeches to the diseased part. By the 11th of October he was so comfortable that he wished to go out; and he went to his master's in Connaught Place.

Two days afterwards, he sent to beg that I would go to see him there. He had brought up, on the preceding evening, during a paroxysm of coughing, about a pint of bright red blood; and he had continued to cough, and to expectorate small quantities of blood. I had him again brought to the hospital on the 14th of October, where he remained, apparently much the same as before he went out. But on the 19th he suddenly expired. The whole duration of his illness had been nine or ten weeks.

We found the heart natural in size and in appearance; the pericardium healthy, and containing no more than the usual quantity of serum. All the cavities were natural in their dimensions, and in the thickness of their walls; and all the valves healthy, excepting one white spot on the mitral valve, which could not have interfered with its motions.

The aorta at its origin was also natural in size; but it began to dilate just before it escaped from the pericardium, and the dilatation continued to the giving off of the left subclavian, where the vessel resumed its proper capacity. The arteries arising from the aorta did not partake of the dilatation; but the sac overlapped and adhered to the external surface of the innominate, for about a quarter of an inch from its origin. This explained a symptom I omitted to mention, viz., that the right radial artery beat much more feebly than the left.

The pouch formed by the aneurism adhered in front, for the space of two inches, to the inner surface of the third rib; and close to the edge of this adhesion there was a small irregular aperture about two lines in diameter, by which the interior of the pouch communicated with the right pleural cavity. Nearly a pint of loosely coagulated blood was found in that cavity, together with a greater quantity of serous fluid than could have belonged to the coagulum. Just above the adhesion to the rib, the pouch adhered to the substance of the lung, over a space about an inch square; and here the parietes of the artery seemed wholly wanting. This doubtless had been the channel of the copious hæmoptysis a week before his death; and it is interesting to observe that the opening of the aneurism into the lung was not immediately fatal.¹ The artery was much diseased, in the usual manner. The right lung was nearly all of it "carnified" by the compression it had undergone.

If this case had not terminated as it did, no doubt the aneurism would have made its way outwards through the ribs, as happened in the very remarkable specimen before you; in which you see that the sternum and five of the ribs have disappeared before the pressure of an aneurism in the ascending portion of the aorta. Sometimes, the tumours that form in this manner, project and attain the size of the head of a full-grown fœtus before they burst.

What can we do in these melancholy cases? Not much. Certain points of practice are so obvious that it is almost superfluous to mention them. I mean the observance of quiet, and the religious avoidance of everything likely to excite or quicken the circulation: bodily exertion, therefore; straining of all kinds; mental emotion; stimulating food and drink. These are not only likely to aggravate the existing mischief, but prove often the immediate cause of the rupture of the aneurism, and of sudden death.

I mentioned, in describing the morbid anatomy of aneurism, that when the diseased vessel begins sensibly to dilate, and more especially when it is protruded into a sac or pouch, the blood begins to coagulate upon the diseased membrane. And it continues to do so, from time to time, in successive layers, so that upon dividing the aneurismal

¹ In the case of the late Mr. Liston, who died of aneurism of the aorta, the fatal issue of the disease was delayed for more than six months after a single occurrence of profuse hæmorrhage from the mouth. The aneurism, springing from the arch of the aorta, was in contact with the trachea, the front of which was thinned, and in three or four places perforated by apertures each large enough to admit a pea. These openings had been effectually stopped by laminæ of coagulated blood; with which one-half of the cavity of the aneurism was filled.

sac, you will see concentric laminæ of firmly coagulated blood. This is clearly a strengthening of the weak place—a reparatory and compensating process analogous to others which we have already had occasion to notice. And our object, here as in other cases, must be not to interfere with the natural attempts towards repair, but to assist and promote them, if we can: till, peradventure, a spontaneous cure has been performed.

This principle has long been distinctly recognized in the treatment of aneurisms that are incapable of relief by surgical means.

But it is much to be doubted whether the principle, so sound in itself, has been judiciously followed out. You have probably heard, or will hear, a good deal of Valsalva's and Albertini's mode of treating aneurisms. It was simply that of bleeding the patient repeatedly, and keeping him perfectly still, and upon as low a diet as was barely enough to prevent his perishing of inanition. The object of this plan of treatment was to facilitate the coagulation of the blood by diminishing its force and velocity, in the hope that at length such a solid barrier might be built up and organized, as would, in some sort, furnish a new wall to the artery in the dilapidated part. When this object had had the best chance of being accomplished; when the patient had been so reduced as to be scarcely able from weakness to raise his hand from the bed, to which he was strictly confined; then Valsalva increased his quantity of nourishment by degrees, until the necessary strength was restored.

Now I quite agree with Dr. Copland in thinking that this practice may be carried, and has been carried, to a hurtful extent. He says that he has seen cases "in which aneurismal tumours had existed for some time without any increase, so long as the patient avoided any marked vascular excitement, and continued his accustomed diet; but when repeated depletions, and vegetable or low diet were adopted, great augmentation of the tumour, and fatal results soon followed."

In truth we shall perceive reason to expect that this would be the case, when we consider, first, that the starving system, and the frequent abstraction of blood, diminish the quantity of red corpuscles in that fluid, rendering it more watery, and less disposed to coagulate; and, secondly, that what is called reaction—or a violent palpitating action of the heart—is very apt to follow repeated losses of blood; and this forcible action of the heart must tend rather to sweep away the existing coagula, than to cause an additional deposit.

A more reasonable and hopeful plan of management, therefore, would, in my opinion, be one which should keep the action of the heart gentle and moderate, and the motion of the blood as slow and languid as possible, without impoverishing that vital fluid. We should husband the materials of repair, and promote the deposit of them where they are wanted. A nutritious but unstimulating diet, consisting chiefly of solid food: perfect repose of mind and body; and a due regulation of the natural functions; with the abstraction of so much blood only as may be necessary to alleviate pain, or to subdue *excessive* arterial action, or to unload vessels which are manifestly oppressed by their contents: these, I humbly conceive, constitute the most rational means of furthering the endeavours of nature towards a cure. Few cures, indeed, can be hoped for in any way. Yet life may be prolonged in these cases, by great care; and the extension of existence even for a month or two, or a week, or a day, may sometimes be an acquisition of the greatest moment.

I have little to say, concerning porticular drugs. Digitalis may, perhaps, be sometimes of use; and the acetate of lead is well spoken of by those who have tried it. I have not had sufficient experience of either of these remedies in the treatment of aneurism to enable me to state anything to you, confidently, in respect of their value.

LECTURE LXIII.

Diseases of the Veins. Phlebitis; adhesive, and suppurative: consecutive scattered Abscesses. Treatment of Inflammation of Veins. Effects of the gradual obstruction of large Venous Trunks.

YESTERDAY I concluded what I had to say, as a physician, respecting diseases of the *arteries*: and this seems as fitting a time as any for taking a final notice of some of the morbid conditions of the *veins*—especially of their inflammation. Already, more than once, brief reference has been made to this important subject; important, whether we consider the large amount of mortal disease which it comprehends, or its wide and intimate relation with general pathology. I should have done better if I had given you, in an earlier part of the course, a more complete and connected account of *phlebitis*, and its consequences. It is this malady which gives to many fatal injuries, and to many, nay to most, of the fatal operations of surgery, their mortal character: it is of surpassing importance, therefore, to the surgeon. The same malady lies at the bottom of the deadliest cases of puerperal fever: it is consequently of the deepest interest to the accoucheur. It occurs also, not seldom, in the practice of the physician, appalling him by its insidious, its rapid, and too frequently its resistless course. Moreover, its pathology, which has been successfully investigated only within these few years, furnishes a key to that of other morbid conditions of great moment.

The first effect of inflammation of a vein is to impede, or to arrest, the passing blood, which, coagulating upon the inflamed surface, adheres to it. In some instances the inflamed coat of the vessel is merely (as Mr. Hunter said) furred over: in others its channel is completely dammed up. The obliteration of a small vein in this manner can seldom have

any serious consequence; but much suffering, and distress, and even death itself, may result from the sudden and continued obstruction of one of the large venous conduits. For example, the painful disorder, called *Phlegmasia dolens*, is caused by a stoppage of the blood in the *femoral vein*. A similar arrest of its current in the *sinuses* of the brain, is a mortal change.

This adhesive form of phlebitis is a local disease. Whatever ill effects it may produce are purely mechanical; and depend upon the closure of the canal. If the organ mechanically affected by it be not a vital organ;—if the system can await the development of a collateral venous circulation;—all, at length, may end well. Sometimes, indeed, as the inflammation gradually subsides, the coagulum is softened and partly reabsorbed, the blood drills for itself a fresh passage through the centre of the plug, and the circulation is restored in its accustomed channels.

This is, fortunately, the commoner form of phlebitis: but sometimes the inflammation advances beyond the adhesive, and into the suppurative stage. Even then the disease may remain a local one. The adhesive process may bound and isolate the suppurative in both directions; and an abscess in the part is then the usual result.

bb. Uterine veins containing phlebolites; *c.* Phlebolite sawed open, exhibiting its concentric arrangement.

But if the suppurating surface of the vein be not so shut off, and pus mingle and circulate with the blood, the disorder is no longer merely local. The contaminated blood is conveyed to distant parts, and the whole system tainted. The malady has become general, and of the most formidable character.

It had long been noticed, as a matter of fact, that collections of pus were not uncommon in various parts of the body, when death had followed mechanical injuries, or great surgical operations. Abscesses of the liver, in particular, were known to be associated with mortal fractures of the skull. Very fanciful reasons were assigned for this coincidence. By degrees it was ascertained that these scattered collections of matter—occurring most commonly in the lungs and liver, but not unfrequently in or near the joints also, in the serous cavities, among the muscles, in the brain, in the eye, and elsewhere—were connected with the introduction of some vitiating secretion, and especially of pus, into the current of the venous blood.

And this step having been gained, fresh speculations arose, concerning the manner in which the internal collections of pus were formed. In the viscera they were usually small, well-defined, surrounded by the healthy tissue of the organ, and several in number. Some maintained, that the pus, in substance, was carried to the parts in which it was found, and there simply deposited. Others were of opinion that the tainted blood created in the system a general tendency to inflammation, which was developed in many places simultaneously. Neither of these suppositions was quite true, neither of them quite false. The pus discovered in the serous cavities was accompanied by unequivocal traces of inflammation in those parts. This alone rendered it probable that the smaller purulent collections were not merely dropped there by the blood in its course (a thing very difficult to conceive), but were the products of actual inflammation, excited somehow in those very spots. And it is now believed that these abscesses *of*, as well as *in*, a part, proceed from suppurative inflammation, provoked by the presence of particles of pus, brought thither with the circulating blood.

I told you before, that minute foreign matters entering the blood, and failing to pass out of it again through the natural emunctories of the body, are liable to be stopped when they arrive at the first network of capillary vessels that lies in their course. Now the blood, circulating in the veins, reaches (much of it at least), in each of its circuits, two such great networks, the hepatic and the pulmonary. Through the pulmonary network all the blood must pass, through the hepatic some of it; and it is there, in the capillary tissue of these organs, that particles of pus, and other material substances, foreign to the blood, and incapable of being eliminated with the customary excretions, are apt to stick, or to be entangled, and to excite inflammation. Some of them, however, in general, pass on, and arriving at the left side of the heart, are transmitted, with the arterial blood, to various parts of the body, there to exercise a similar deleterious influence.

Such was, and is, the theory: and it has been tested and confirmed by direct experiment. Inasmuch as the conveyance of the *pus* cannot be traced by the eye, nor the manner of its being collected into an abscess demonstrated, except by inference, Cruveilhier introduced *quicksilver* into the veins of animals; a metal which is liquid, and divisible into very minute particles, and which exerts no chemical agency upon the vital fluid. When the mercury was inserted into the veins which concur to form the vena portæ, the whole, or the greater part of it, was arrested in the liver. In that organ, the animal being killed a certain time after the introduction of the metal, small, roundish, red spots were always discoverable, which passed gradually into little abscesses surrounded by a halo of inflammatory redness; and in the centre of each red spot, and of each abscess, lay a minute globule of mercury. A few similar points of suppuration were usually to be seen in the lungs also. But when the quicksilver was put into the blood in its direct course towards the vena cava, then it was in the lungs that these points were either exclusively detected, or at any rate most numerous.

You must, I think, perceive how strictly these experiments bear upon the rational humoralism acknowledged at the present day. If pus, and mercury, may thus be distributed to particular organs, and thus excite circumscribed inflammation, so doubtless may other extraneous impurities—introduced by the poison of what is called good living, by the respiration of foul air, and in various other ways—reach, and settle in

different parts of the body (the liver, the lungs, the kidneys, the joints), and there produce, if not inflammation and pus, yet such changes at least as spoil the texture of the organ, and pervert its healthy office. That cancer is propagated in this way we have heretofore seen reason to believe. In all probability the deposit and increase of tubercles fall under the same law. There is however this remarkable difference between tubercles and phlebotic abscesses, that the former occupy chiefly the upper portions of the lungs, while the latter are generally most numerous in the lower lobes.

Suppurative phlebitis—with its horrible effects—is liable to arise, not only after severe but also after slight injuries; from the trivial as well as the grand exploits of surgery; nay, spontaneously, as it were, without any local hurt, under the agency of natural causes, such as exposure to cold. And the part in which the phlebitis occurs has some influence, as you will now understand, in determining the principal seat of these scattered abscesses. When they succeed amputation of a limb, or fracture of the skull, or the interference of surgery with varicose veins, or (as they may) even the simple operation of phlebotomy, they are likely to be most numerous in the lungs. But they are more conspicuous to hasty observation in the liver than in the lungs; and that is why hepatic abscess was supposed to have some special connexion with injuries of the head. Morgagni, however, long ago pointed out the fact, that other parts also were affected in those cases. Again, we may expect to find these disseminated abscesses chiefly in the liver, when suppurative phlebitis occurs in any of the tributary veins of the vena portæ; when it supervenes, therefore, upon operations involving the intestines—operations for the release of hernia, for healing fistula in ano, for the cure of piles.

It is, however, very common for the poison to pervade the whole body, and for abscesses to form in various other situations, as well as in the lungs and liver. I once saw a young woman die, in the Middlesex Hospital, from phlebitis, with large abscesses in many parts, and especially in the joints, after the simple excision, with scissors, of some small spongy irritable growths about the orifice of her urethra.

Two or three instances of suppurative phlebitis, unconnected with any known hurt, and originating apparently in exposure to cold, have fallen under my own observation: but I prefer giving you the following short case, with the details of which I have been favoured by Dr. Malden, of Worcester.

Miss ———, a teacher in a ladies' school, was attacked, after exposure to wet and cold, with acute pain, heat, and redness, in the front of the left fore-arm. Mr. Cole, an eminent surgeon, of Bewdley, by whom she was at first attended, discovered inflammation following the course of the cutaneous veins. Upon its subsidence the veins were left like hard cords. Soon after, the right arm was affected in a similar way: and next, both the lower extremities, which became anasarcous. All this was attended with paroxysms, simulating those of tertian ague; exhausting sweats; diarrhœa; and a frequent feeble pulse. At the end of a month, deep-seated fluctuation was detected in the right thigh, three inches below Poupart's ligament. The abscess gradually approached the surface, and was opened, and more than three pints of very fetid pus was discharged. The wound never closed, and she sank, exhausted, a month after it was made.

There was no pain, premonitory or attendant, connected with this formation of matter.

The abscess was traced, after death, upwards, behind the muscles of the pelvis, as far as the sacro-iliac symphysis, where the bones were extensively carious.

Many of the superficial veins, both of the upper and the lower extremities, were found to be completely obliterated by adhesive inflammation, or sealed up by coagula of blood.

This spreading and morbid inflammation of veins is sometimes so remarkably prevalent, as to partake of the character of an epidemic disorder: and this, its occasional prevalence, appears to be owing to some peculiar condition of the atmosphere—or rather to some predisposition of the human body, engendered by the operation of influences which are probably atmospheric. During such periods prudent men refrain, if they can, from the performance of surgical operations.

The view which I have now set before you of suppurative phlebitis, and of its distant effects, involves some apparent difficulties, and some curious questions. A short consideration of these may serve to throw a clearer light upon the main subject.

First, then, how is it—if indeed the disseminated abscesses result from the introduction of pus into the blood—how is it that we do not meet with them oftener? Pus is absorbed, in numberless instances, without the occurrence of any such formidable consequences. We see great abscesses disappear spontaneously, and yet no other smaller scattered abscesses ensue. Does not this fact invalidate the theory of the cause and formation of such distant points of suppuration? No. It seems that, for their production, pus as such, pus in substance, pus in the mass, must be received into the veins, and circulate with the blood. The pus which is taken up by ordinary absorption, is altered, probably by that process, before it reaches the blood: at any rate it has not the same mischievous and fatal effect.

You may here inquire in what manner pus gets into the circulation, in consequence of an amputation? Is it not absorbed from the suppurating stump? I conceive not. Supposing the amputating knife to cross and sink into an existing abscess, and to divide a vein—then, indeed, pus might be sucked into the vein, and the usual consequences follow. But the veins that lead to, or rather from, a stump, become blocked up, and impervious, from adhesive inflammation, or from mere coagulation and adhesion of the blood in them, before the stump has had time to suppurate. How then does the pus ever find admission? No doubt it is a product, in this case also, of phlebitis. The interior of a vein inflames, and goes on to suppuration: and the pus which it pours forth mingles, as pus, with the circulating stream.

Indeed these scattered abscesses appear to originate almost always in phlebitis. Such is the opinion of my colleague, Mr. Arnott, who has contributed a valuable paper on this subject to the *Medico-Chirurgical Transactions*. Such is also the opinion of M. Cruveilhier. It has been objected that, in some fatal cases of this kind, no phlebitis could be detected; that the principal veins have been diligently traced, yet no vestige of suppuration, nor even of adhesive inflammation, has been visible. To make this objection valid, *all* the veins throughout the body should be scrutinized; and that has seldom, I fancy, been done. I have known several instances, in which most of the larger trunks were searched in vain, till at length a short track of one of them, an inch or two perhaps, was found, bearing marks of having been inflamed. You must not conclude therefore against the antecedent existence of phlebitis, until you have examined every vein in the soft parts of the body: no, nor even then. You must go deeper than the more obvious veins. There is good reason for believing that the *bones* and their veins are often the seat of the primary mischief, the fountain from which the pus, which thus renders the blood a poison, first proceeds: the veins, for example, of the *diploë* of the skull, when scattered abscesses ensue upon injuries of the head; the veins of the bones of the extremities after unsuccessful operations. There is yet another explanatory supposition applicable to some cases. All local traces of the primary inflammation may vanish before death, while the vital powers are being undermined, and about to sink under its secondary effects.

Cruveilhier repeatedly performed the following experiment, and always with similar results. He introduced crude mercury within the hollow shaft of the thigh bone of a living dog. When the quantity was considerable, death occurred in a few days, and the metal was found strewed thickly through the lungs, each globule occupying a capillary branch of the pulmonary artery, and surrounded by a small sphere of inflammatory redness. When the quantity was minute, the animals lived longer, and little abscesses, enclosing each a particle of mercury, were then discovered in the same organs. The mercury he supposes to have found a direct entrance into the blood, in these cases, from the cancellous portion of the bone, and through the same channel it seems to be that pus often enters the circulation. You may remember my relating some fearful examples of scattered abscesses, supervening upon chronic disease of the bones of the ear. Cruveilhier states that, having been present at the examination of the body of one who had sunk after amputation of the leg, and whose lungs were full of little abscesses, he sought, without success, for some inflamed vein: but upon dividing the tibia and fibula, he found the spongy extremities of these bones infiltrated with pus. Here, beyond question, had been the source of the visceral mischief.

Occasionally, however, these disseminated abscesses may acknowledge another source than inflammation of a vein. I showed you, in the last lecture but one, that

suppuration may occur within the heart, and pus be poured directly into the circulating stream of blood. But this can seldom happen.

The local phenomena, when a superficial vein of some magnitude is inflamed, are pain and tenderness in the course of the vessel, which, in the adhesive variety of the complaint, is soon converted into a tangible, hard, and sensitive cord. Whether the vein be near the surface, or deeply seated, there is usually more or less œdema of the areolar tissue of the part. Phlebitis of this kind has been sometimes confounded, I believe, with inflammation of the lymphatic absorbent vessels. You distinguish the latter by the slenderness of the painful cord; by its position, which is still more superficial than that of a subcutaneous vein; by the number of little knots which diversify its course; and by the streaks and patches of bright inflammatory redness which appear along the same track. Dr. Graves remarks (*Clinical Medicine*, p. 454), that inflammation of the lymphatics "is seldom continuous, but is developed at certain insulated points." Velpeau has laid down the following aphoristic distinction between the two. "Angioleucitis is seen, but not felt, while phlebitis is felt rather than seen: so that the complaints might be discriminated even with closed eyes."

In the suppurative form of phlebitis the general symptoms take the lead. A sudden change in the aspect and manner of the patient often marks the commencement of the constitutional affection. The formation of pus in separate and often distant parts is rapid, and frequently unannounced by any local pain. When however the joints, or parts near the joints, are the seat of suppuration, much soreness is complained of, and the malady is liable to be mistaken for rheumatism: and when the serous cavities are implicated, the pain is sometimes severe. Suppurative phlebitis is commonly attended in its progress with repeated shiverings, which are sometimes periodical; and with profuse sweats, and occasionally with copious and very unnatural discharges from the bowels. These last have been noticed in animals soon after the introduction of pus, or of putrid matters, into their veins. Nature seems to attempt to eliminate the poison in this way: and where the quantity of pus so introduced has been small, the attempt is now and then successful. But in general there is a continual supply of the noxious substance, and the system is irrecoverably infected. The skin acquires a yellowish hue, as if the patient were faintly jaundiced. Here and there upon the surface of the body patches of erysipelatous inflammation are apt to appear; and sometimes, of superficial gangrene. The pulse is almost always rapid. In most cases, but not in all, symptoms occur resembling those which mark low forms of typhus fever. Very constantly there is great agitation, and a signal disturbance of the nervous system.

I have called this purulent infection of the blood a formidable disorder: in truth it is almost always a fatal disorder. Yet that it is not inevitably mortal I know by a case which has recently occurred in Mr. Arnott's practice at the Hospital, and which he permits me to mention. He had occasion to amputate the fore-arm of a man whose hand had been crushed by machinery. Two or three days after the operation, the patient's pulse quickened, and he had a severe rigor. These two circumstances led Mr. Arnott to apprehend the supervention of phlebitis; and accordingly one of the large, superficial, visible veins of the fore-arm became swollen, hard, and tender. Leeches were applied along its course; and the parts were kept covered with the water dressing. In no long time an abscess formed in the other arm: next, a large one in the back, from which twenty ounces of pus were evacuated; then one beneath the glutæi muscles of the buttock, on both sides—each of these two contained about sixteen ounces. In short, dating between the beginning of October and the middle of December, no less than seven collections of matter presented themselves in various places. The last of them was in a very unusual part, beneath the man's tongue, in the ordinary situation of ranula, for which, indeed, it was at first mistaken. In every instance the pus was let out as soon as possible, and the main feature in the general treatment was the administration of opiates, and of wine, with a liberal allowance of good beef-tea in the earlier stages, and of meat afterwards. This man recovered; and was seen in the month of May following, in perfect health. The case is extremely interesting. It shows, I say, that suppurative phlebitis, even when it strews consecutive inflammation and suppuration throughout the body, is not absolutely and hopelessly fatal. Whether abscesses, from this cause, distributed in the lungs or liver, are capable of repair, I cannot tell you. Under the treatment employed, the

inflammation of the vein in the arm gradually subsided. All outward evidence at least of its existence, all induration even, disappeared; and presumptively all inward evidence too. So that, had this patient sunk, late in the course of his disorder, under the multiplied secondary abscesses, his venous system might probably have been searched in vain for any remaining traces of phlebitis: and yet we know that at one time he *had* phlebitis, more severe and extensive than belongs to the natural and kindly healing of every stump.

The treatment found most suitable in phlebitis has just been briefly indicated; local depletion when the inflamed vein is accessible; regulation of the bowels; strong animal broths and wine to support the strength; opiates to tranquillize nervous irritability and restlessness. Our object is in the first place to subdue and resolve the inflammation: or at any rate to prevent its passing beyond the adhesive stage. To this end, the vein being obvious and superficial, we apply leeches, cold lotions, or fomentations.

[In cases of phlebitis from venæsection, the late Dr. Physick recommended the application of a blister over the orifice in the arm, as soon as the inflammation commences, the orifice itself being first defended by a plaster of simple cerate spread on linen. He found this to be invariably beneficial in causing the arrest of the inflammation. Dr. Dorsey also found a blister thus applied to produce always a good effect; and in a case related by Dr. Evans, (*Transac. College of Physicians of Philadelphia*, vol. ii., p. 106,) the good effect of blisters in a case of spontaneous phlebitis, was strikingly evinced.—C]

During the progress of the malady, especially when suppurative phlebitis is prevalent, it would be unsafe to cut into a large vein, lest, by that slight violence, we establish a fresh local phlebitis. Indeed, after the suppurative form has once been set up, general blood-letting does no good; but, on the contrary, impairs the power of the system at large to struggle against the disease.

The *obliteration* of a large vein, whether by adhesive phlebitis or in any other way, is perilous in proportion to its magnitude, and to the rapidity with which its complete occlusion has been effected. The gradual stoppage of even the largest—the primary venous trunks, the venæ cavæ—admits of some degree of compensation. In one instance of this kind, which I briefly described yesterday, and which I myself witnessed, the *superior* cava was flattened, and its channel completely effaced, by the pressure of an aneurismal tumour: in another, which I mentioned formerly, on Mr. Kiernan's authority, an immense varix of the superficial veins of the abdomen supplied to the returning blood the passage denied to it, in its natural course, by the partial obliteration of the *inferior* cava. To impress upon your recollection the ordinary phenomena that result from these grave derangements in the hydraulic machinery of the body, I will state here, from my hospital case-book, the outlines of two additional examples of a similar character.

James Buck, aged thirty-three, was admitted on the 6th of March, 1838. The appearance of this man was very remarkable. His countenance was swollen and livid; his eyeballs projected; his lips, the end of his nose, and the rims of his ears, were of a deep purple colour. It was manifest that the blood did not freely descend from the head. Further evidence of this became apparent when the trunk of his body was uncovered. The throat was very broad, full, and tumid, like that of a goitrous person, yet the swelling was not owing to enlargement of the thyreoid gland, nor to œdema; but felt firm and fleshy. The jugulars were distended; and the whole surface of the thorax in front, with that of the shoulders, and of part of the abdomen, was thickly overspread with a network of prominent veins. The external mammary veins were seen to communicate freely with veins proceeding from the neck on each side, with the veins of both the upper extremities, and with the epigastric veins from beneath. Here and there were patches of minute purple varicose branches, crowded closely together.

He told us that whenever he stooped down, to tie his shoe-strings for instance, he became giddy, his head swelled, and his face and ears grew black: that he was very nervous, easily flurried, and dreamed much, thinking that he was flying in the air, falling down precipices, and the like. He had not noticed any swelling of the face

or throat until three weeks previously; and he had never, he said, had a day's illness before. He knew of no cause for the complaint; had been making no extraordinary bodily effort; had never suffered rheumatic fever. He professed, also, temperate habits, but he had been a soldier, and afterwards a pugilist, and his wife informed me that he had led an irregular life.

The evidence I say was strong, of some obstruction to the return of the blood through the superior cava. Now such obstruction is most commonly produced by intra-thoracic tumours—sometimes by carcinomatous, much oftener by aneurismal tumours. There were no circumstances to make it likely that malignant growths existed; but there were circumstances which corroborated my first suspicion, that the symptoms were dependent upon aneurism of the aorta, or of one of its primary branches.

There was indeed no external prominence, no pulsative or other swelling, no aneurismal whiz, to guide us to this diagnosis. Upon careful and repeated auscultation of the chest, the murmur of respiration was found to be in some parts feeble and unequal. This might consist with the presence of any kind of tumour. The heart's action was heard, and felt, strong and heaving, in the proper place, beneath the left nipple. To the right of the sternum also, and near the middle of its upper portion, one's ear was distinctly jarred at each systole of the heart, though with less force than in the præcordial region. But in the space intermediate between these two spots, no such jarring sensation was perceptible, although the heart could be heard, beating with a slight bellows-sound. Moreover, the right radial artery was considerably weaker and smaller than the left. This showed that the innominata was interested in the disease. The symptoms, taken together, left no doubt on my mind that there was an aneurismal pouch beneath the sternum, where the jar was experienced. I have gone somewhat into particulars to show you how confidently sometimes, by close observation, you may pronounce upon the condition of parts which you can neither see nor touch.

All that could reasonably be hoped for from medicine, was postponement of the evil day. To relieve the oppressed blood-vessels by taking away part of their contents, by freely purging the patient, and by setting his kidneys at work—this was what was to be attempted; and this was done. He was repeatedly cupped, and always with most sensible relief to his feelings, the blood flowing copiously. Purgatives and diuretics also acted well; and so much was the man benefited by these measures, that *twice* he left the ward, and became an out-patient.

About the middle of June a new symptom arose—severe pain extending from the right collar-bone across the shoulder. He died on the 10th of July. Three or four days before his death, he had rigors and extreme dyspnoea, complained of pain over the whole thorax, and declared that his “heart seemed on fire.” These symptoms were caused by the supervention of pericarditis, which speedily proved fatal. A thin layer of recent, reticulated lymph was found covering a considerable extent of the surface of the heart.

The body was examined by Mr. Shaw, after injection of the veins, and of the thoracic duct.

There was a large aneurism of the arteria innominata; of which I omit all particular description, my present object being to draw your attention to the state of the veins. The two great trunks that, coming from either side, unite to form the vena cava superior, were completely closed up, as well as the corresponding portion of the cava itself, which was lost and confounded in the walls of the aneurismal sac. The subclavian veins were pervious up to the point where they joined the internal jugulars, but no further. The preparation of these parts, which is before you, and the rough diagrams which I here exhibit, will aid your comprehension of the mode whereby the blood, descending from the head, found its way at length, through many circuitous channels, to the heart. The larger deep-seated compensating veins were not greatly magnified, but the number of the smaller branches was much augmented. The *vena azygos*, for example, was very little above its usual size; yet it was apparently provided with a greater number of considerable branches than are commonly observed under natural circumstances.

As the veins into which the trunks of the absorbent vessels discharge their contents were obliterated, it became interesting to examine the state of these vessels, and

of the lymphatic glands. But the condensation and confusion of all the parts around the tumour rendered it difficult to trace the thoracic ducts. The glands were remark-

Fig. 97.

A Obstructed veins.

B Seat of the right auricle.

C Thoracic, pectoral, and mammary veins, conveying the blood in a contrary course to its usual direction, and anastomosing with the intercostal and epigastric veins.

ably large, of a purple colour, and gorged with bloody serum. The fulness of the neck, noticed during life, was occasioned by this turgescence of the *glandulæ concatenatæ*. Large glands were seen studding the walls of the aneurism, and adhering to the great vessels connected with it: *i. e.* in situations where, under ordinary circumstances, such glands, from their minuteness, can scarcely be detected at all.

With this case, contrast the following:—

Harriet Baldwin, thirty-three years old, was admitted, December 29, 1840, anasarous as high as the hips, and with an enlarged abdomen. The swelling had begun, she said, a fortnight before.

She complained of cough, and of expectoration, which was sometimes tinged with blood. She could not lie down in bed for dyspnœa. Her urine was scanty and dark-coloured.

She told us that she had dropsy, quite as bad, five years ago, of which she was cured in St. Bartholomew's Hospital.

All this we learned in the admission-room. The next day, when she was in bed, we learned a good deal more.

The large abdomen did not owe much, if any, of its bulk to ascites. It contained a palpable tumour, filling the right hypochondrium, and extending thence far beyond the umbilicus to the left, and into the right groin. This tumour, from its situation, and from the continuous dulness elicited by percussion from the right mamma downwards over its whole extent, was evidently formed by the liver, much enlarged, and out of its place.

But, besides the tumour, the abdomen presented on its surface a very singular appearance. Two zigzag lines of large, varicose veins ran up its middle, near the right edge of the linea alba. These, which were evidently the epigastric veins, inosculated above with the mammary. Large but straighter veins, wandered over the front of the thorax on both sides.

The swollen legs of this woman were quite purple from innumerable clusters of small varicose veins.

Other symptoms also there were, but I pass them by as irrelevant to my present subject. It was plain that the current of the blood along the vena cava inferior was suffering impediment. That vessel was presumably compressed, perhaps rendered totally impervious, by the superjacent tumour. The existence of the tumour; the great œdema of the legs, compared with the slight amount of liquid in the cavity of the belly: the varicose state of the cutaneous veins of the legs; and, above all, the remarkable condition of the superficial veins of the abdomen:—these were the evidences. The blood from the lower extremities passed mainly by the way of the intercostal and subclavian veins, to the heart. Death took place on the 19th of January, 1841. A part of the liver appeared perfectly healthy; another part contained a prodigious quantity of hydatids. When removed from the cyst which had contained them, they filled a large wash-hand basin. The sides of the inferior cava were pressed together by the tumour, and its channel was thus completely closed up for the space of three inches.

In each of these two cases, the closure of the great venous trunk was effected gradually, as the compressing tumour augmented; and time was afforded for the development of collateral supplementary channels. In both cases the superficial veins of the thorax and abdomen contributed largely to supply the growing needs of the system: but the stream of returning blood ran oppositely in the two cases; from above downwards in the first, from below upwards in the second. The direction in which the blood in the veins is moving can, of course, be always readily ascertained; and this might furnish a test, were other tokens wanting, whereby to determine whether the obstruction lay in the superior or in the inferior cava. And there is another circumstance worthy of remark, and of which the same use might be made. In the first case, the dilated veins of the thorax were tortuous, those of the abdomen direct. In the second this was reversed; the epigastric veins were singularly sinuous, the mammary veins were straight. In other words, those veins were, in each instance, contorted and winding, in which the actual course of the blood was retrograde. The vessels were bent and twisted as the current forced its backward way against the opposing but ineffectual barrier of the valves.

It is impossible, I think, to find more clear evidence than these interesting cases exhibit, of the power inherent in the animal body of rectifying, to a certain extent, its own accidental derangements. You cannot, under such circumstances, overlook the existence, or mistake the tendency, of a *vis medicatrix naturæ*.

LECTURE LXIV.

Asthma: its nature; complications; exciting causes; and treatment. Diseases of the Œsophagus: Inflammation; Stricture; Spasm; Dilatation.

I MUST not leave the subject of thoracic disease without saying a word or two respecting *asthma*; a complaint which might have been properly arranged among the *nervous spasmodic diseases*, in a former part of the course. But I purposely deferred speaking of it, because, though in many instances purely spasmodic, and independent

of any discoverable faulty structure, it is still more often connected with organic diseases of the heart, or of the lungs; which diseases had not then been described.

I scarcely need caution you against the vulgar error of calling all kinds of difficult breathing by the name of asthma. You will be constantly meeting with persons who, labouring under some permanent embarrassment of the respiration, tell you they are asthmatic. They conceive that asthma is simply an inconvenient, and not at all a dangerous affection; and they please themselves with the notion—consumptive patients and their friends do this continually—that they are *merely* asthmatic. Asthma is dyspnoea, but dyspnoea is not *necessarily* asthma.

Asthma may be defined as being—great difficulty of breathing: occurring in paroxysms; accompanied by a loud wheezing sound of respiration; passing off, after some hours, with more or less mucous expectoration; and unattended with fever. And these paroxysms of dyspnoea are believed to depend upon a spasmodic constriction of the bronchial tubes.

To go rather more into detail: the phenomena which constitute and characterize a fit of asthma, are somewhat as follows:—The patient, if he have previously suffered under the disease, has usually some well-understood warnings that an attack is hanging over him. Loss of appetite; frequently much flatulence and eructation; languor, irritability, drowsiness, oppression, chilliness; and he goes to bed ill and uncomfortable. The dyspnoea comes on generally after midnight, about two or three o'clock in the morning; often during sleep; and the patient wakes with a sense of tightness and constriction about the chest, and an inability, as it seems to him, freely to expand it. He is obliged at once to rise up; and he sits, leaning forward, with his knees drawn up, his elbows on his knees, and his head supported by his hands, labouring for his breath, and making a wheezing noise so loud as to be audible at a considerable distance. He experiences a strong desire or necessity for fresh air; opens the door of his room and goes out upon the staircase, or flies to an open window, even in very cold weather; and remains there, with his head out, sometimes for hours. That he can do so with impunity furnishes a strong presumption that it is the nervous system which is principally affected in these cases. His extremities at the same time are usually cold, and his countenance is distressed and haggard: while the trunk of his body may be wet with perspiration. Sometimes the face is a little flushed and turgid; but more commonly it is somewhat pale, and shrunk. The pulse is often small, feeble, and even irregular; and in many instances there is much palpitation of the heart. At other times the pulse remains undisturbed. If urine be passed, as it frequently is, at the beginning of a fit of asthma, it is copious and watery, pale, clear, and without smell, like the urine of hysterical women. The bowels are also sometimes relaxed, with “something (as Sir John Forbes observes) of the impatient hurry and imperfection of spasmodic action.” There may be some propensity to coughing, but the patient can hardly achieve a cough; and is so engrossed with his breathing, that he can speak in an interrupted manner only, with difficulty and uneasiness. He has not, however, in general, any misgivings about the event of the attack, but looks forward with hope to the expected termination of the paroxysm.

“These symptoms often continue for many hours together; and particularly from midnight till morning is far advanced. Then, commonly, a remission takes place by degrees. The breathing becomes less laborious, and more full: so that the person can speak or cough with more ease. And if, as is usually the case, the cough brings up some mucus, the remission becomes immediately more considerable, and he falls into a much-wished-for sleep.”

Paroxysms of this kind will often continue to recur for many nights in succession; remitting at length in their severity: and ceasing for a period, altogether.

During the intervals between these paroxysms, in the daytime, the patient *may be* perfectly well; but he seldom *is* so; though so great is the difference between his condition during the remissions, and his condition in the paroxysms, that he declares, and perhaps fancies, that he is quite well. You will mostly find, however, that he is short-winded; that he does not utter many words of a sentence before he pauses to take breath; that slight bodily exertion hurries his respiration; and that he is not easy in a horizontal posture, with his head low.

Although the dyspnoea is thus intermittent, or remittent, you are not to suppose that the paroxysms recur with the regularity of those of ague. The interval is of

uncertain duration; and the circumstances of the paroxysm differ in different instances. I may remark also, that when the paroxysm ceases, with little or no expectoration, the case is said to be one of *dry* asthma: when the expectoration is copious, it is *humid* or *humoral* asthma.

Now this, I say, is looked upon as being essentially a spasmodic affection. Upon what grounds?

Why, in the first place, the patients have a *sensation* of constriction in the chest. An old gentleman whom I saw lately, and who is subject to fits of asthma, made use of the term *cramp* when he described what he felt about the thorax; and his attacks were always accompanied or succeeded by *actual* cramp of the muscles of the calves of his legs. This is no uncommon circumstance, this co-existence of decided spasm in other parts; and it throws some light upon the nature of the disorder. Again, the rapidity with which the dyspnœa comes on, and the suddenness with which it often abates, resemble the caprice of spasm. The supervention of extreme, sometimes enormous flatulence, and the secretion of hysterical urine, mark also the nervous character of the symptoms. So likewise do the *juvantia* and the *lædentia*, as I shall presently explain further; the affection being suddenly produced by certain causes of irritation, and even by mental feelings—suddenly relieved, sometimes, by medicines which are reckoned antispasmodic. If we add to these considerations the fact that the dead bodies of asthmatic patients have often, on being examined, presented no vestige whatever of disease, either in the lungs or in the heart, we obtain very strong presumptive evidence, that the phenomena attending a fit of asthma may be the result of pure spasm.

But if this be so, what are the muscles thus fixed in spasmodic contraction?

You are doubtless aware that the air-tubes are encircled with a series of little fibres, or bundles of fibres. I have more than once shown you these, exaggerated by hypertrophy, in the larger bronchi. They have been traced, by Reissessen, in tubes of very small diameter. Laennec states, that he had distinguished them in bronchial ramifications less than one line across. Now, supposing these circular fibres to be muscular, it becomes at once, and *à priori*, likely that they, no less than other muscles, should be liable to spasm. And the phenomena of asthma prove, to my mind, that they are so. Analogy would say that the fibres, thus disposed, are slender muscles, similar to those which surround the intestines and the urinary bladder: and the microscope, scrutinizing their minute texture and appearance, asserts that they are actually muscles, of the unstriped kind; like other involuntary muscles subserving the organic life. This fact—which, I am aware, has been doubted—I state upon the authority of Professor Todd and Mr. Bowman; both known to you all, as faithful and expert observers. But a test, less fallible than the microscope, has practically settled the question. Dr. Williams has demonstrated, by a set of ingenious and satisfactory experiments, that the lungs and air-tubes are actually *contractile* to a very considerable degree, under electrical, chemical, and mechanical stimuli. The contractions take place steadily and slowly; and are followed, as soon as the stimulus is withdrawn, by an equally gradual relaxation. This is very like tonic spasm. The contractions were rendered apparent by means of a bent glass tube, containing coloured liquid, and adapted to the windpipe of an animal just deprived of life. The column of liquid in the glass tube would of course be readily moveable by any contraction of the lungs and air-tubes, causing pressure of the included air against it. In one of the experiments, “on passing a galvanic current from the margin of the lungs to the insertion of the tube in the trachea, the fluid rose quickly, but gradually, nearly two inches; sank speedily on breaking the contact; again rose upon completing it; but fell slowly when the current was continued for some seconds;” *i. e.* when the irritability of the tissues was temporarily exhausted. Temporarily, I say, for on waiting two or three minutes between each application of the galvanism, the liquid was raised again and again for upwards of an hour; till, in fact, the organic life was extinct. Is not all this exceedingly like the behaviour of parts acknowledged to be muscular, under similar influences?

The phenomena were not occasioned by any general shrinking of all the pulmonary tissues. For when the lungs were cut across by sharp scissors, at right angles to the air-tubes, and the open sections of these tubes were galvanized, they were *seen* to contract to one-half of their former diameter; and even to become smaller than that.

The contraction was the most distinct in the middle-sized tubes, they being about the bigness of a straw; but it was sensible enough in the trachea, which was sometimes so far reduced in dimensions, that the ends of its cartilaginous rings came together.

A foreign experimenter, M. Valentin, carries us a step nearer to the full solution of this interesting question. He found that the rings of the trachea could be made visibly and distinctly to contract, *by irritating the par vagum*.

The natural function of the contractile fibres is probably (as Dr. William Gairdner suggests) that of gradually propelling outwards, by a kind of peristaltic movement, the mucous secretion which is constantly oozing, in small quantities, into the smaller air-tubes.

Upon the whole we may safely conclude that asthma is one of the spasmodic disorders of the excito-motory system of nerves. I believe, moreover, that, as in most other disorders of the same class, the spasm may be of centric, or of eccentric origin. In the eccentric form, the par vagum is doubtless the afferent nerve; and the impression it conveys to the medulla oblongata is reflected, through associated motor nerves, upon the bronchial muscles. The centric variety results from a similar impression originating in the nervous centres: which respond, mysteriously, to certain feelings of the mind.

I have never had a favourable opportunity, since I became aware of the value of auscultation, of listening to the sounds of the breathing during a paroxysm of pure spasmodic asthma. But they who have enjoyed such opportunities declare that no respiratory murmur, or very little indeed, can be heard. And an attentive inspection of the outside of the chest shows, that amidst all the tugging and heaving for breath, the expansion of the thorax is very limited. The patient cannot open his lungs as it were: and what air does get in, has a difficult and narrow passage, as the wheezing noise demonstrates. Laennec affirms, that if the patient, after holding his breath nearly as long as he can, attempt a quiet and gentle inspiration, the spasm may be often overcome as if by surprise; and, for a few seconds, the entrance of the air into the cells may be heard in a clear and even puerile sound. If this be true, it is a strong additional proof that the obstruction to the admission of air was really owing to a tonic contraction of the little muscular fibres of the bronchi and their ramifications.

The hereditary nature of asthma is perfectly consistent with the same theory. It is one of the maladies which are distinctly transmitted—the disposition to them, I mean—from parents to children. And, like other spasmodic disorders, it facilitates its own return. When it has once occurred, it seldom fails to happen again and again.

But though I believe, for the reasons I have now mentioned, that asthma, in the restricted sense of that term, is purely a spasmodic affection; yet I know also that it is very frequently indeed combined with organic alterations within the thorax. These changes of structure are to be regarded as so many strongly predisposing causes. They induce a readiness to take on spasmodic action: and some of them are perhaps aggravated, or even produced, by the fits of asthma, upon which they afterwards react injuriously. Judging from my own experience, I should say that genuine uncomplicated spasmodic asthma was *rare*.

The organic diseases with which spasmodic asthma is often found connected, are principally emphysema of the lungs, and structural changes in the heart and great blood-vessels. It is extremely probable that the first step towards the production of the spasm, consists in some altered condition of the *circulation* through the lungs. The chilliness of the surface, and the sensation of want of air, make it likely that the blood accumulates in the lungs at those times: that there is congestion of the membrane, as well as spasm of the circular fibres. And it would seem that, in the humoral asthma, the congestion is relieved by a copious secretion of mucus; and that, with the congestion, the spasm also subsides and disappears. You will observe that very generally the paroxysms come on during the first sleep: at which time, as Dr. Alison has suggested, “the blood is perhaps in fullest quantity, its movements slow, and its congestion in internal parts easiest, because it is least solicited to the organs of sense or locomotion.” But there seems to be another reason for this remarkable circumstance. Respiration is mainly an automatic act; yet it also obeys the will. During sleep this moderating influence of the will is suspended. Those changes of posture, and those voluntary alterations in the rate of breathing, which are wanted to balance and correct the commencing derangement of the pulmonary circulation, and

which are prompted at once during the waking state, do not occur; until at length the derangement reaches that pitch at which it provokes spasmodic contraction, and rouses the sufferer.

This same congestion, leading to spasm, sometimes passes into a slight form of inflammation; and we have symptoms of bronchitis. And these symptoms may remain manifest even during the intervals of the paroxysms.

Many of these asthmatic patients have just healthy lung enough to breathe with, in tolerable ease and comfort, under ordinary circumstances; and dyspnoea is brought on whenever even a slight additional demand upon the respiration any how arises. Hence, as I stated before, flatulent distension of the intestines, undue repletion of the stomach by an excessive meal, the recumbent posture, all of which cause pressure against the under surface of the diaphragm, may suffice to bring on the fit. Hence also, probably, in part, its frequent occurrence in the night-time.

In like manner, any extraordinary task imposed upon a heart which is barely equal to its functions while the body is in repose, may induce a paroxysm of asthmatic dyspnoea.

Asthma is a disorder which is incident to both sexes, but it is much more common in men than in women. It is incident to all ages also; but it belongs more to adolescence, and to the middle portion of life, than to its extremes. It is not, I think, a common disease prior to the age of puberty: yet instances of it do occur at an earlier period than that. I have lately seen a boy of eight or nine, who has had several well-marked attacks of pure asthma. Nor does it often *begin* to show itself in old age. Sometimes, after plaguing the subject of it for several years, it leaves him altogether. The chronic dyspnoea, with occasional irregular exacerbations, which is so frequent a disorder among old people, and which always depends upon organic disease, is not to be confounded with true asthma. It is said that asthmatic persons are exempt from phthisis: and I understand that one physician in this town, who announces that consumption is curable, maintains the doctrine of the incompatibility of phthisis and asthma; and endeavours to bring about the latter, that he may protect his clients from the former. It *may* be that persons affected with genuine asthma seldom become the victims of pulmonary consumption: but I am sure the rule is not universal. One of my earliest friends had from time to time, while we were school-fellows, and long afterwards, the most exquisite fits of spasmodic asthma. At length, when he was between thirty and forty years old, they wholly ceased: whereupon he greatly congratulated himself. But they only yielded before a worse disease. He began in a few months, to spit blood: and in a few months more he died of well-marked phthisis. Our lamented principal, the late Mr. Rose, afforded another sad example of the same sequence. And I have known two or three families in which one individual was subject to asthma, while others were scrofulous and phthisical.

The exciting causes of the asthmatic paroxysm are manifold; and some of them curious. They seem to be reducible to two classes. 1. Particular states of the atmosphere, which irritate or offend the mucous surface of the air-passages: or rather, some of the fibrils of the par vagum. 2. Certain subtle influences which affect in a peculiar manner the nervous system. All the known exciting causes of catarrh are therefore likely to bring on attacks of asthma in the predisposed. But there is a singular caprice in asthmatic patients in this respect. Some persons, subject to the disorder, are unable to breathe in the thick smoky atmosphere of London; require a high and clear situation; and respire easiest in the difficult air of the keen mountain-top." Others can nowhere breathe so comfortably as in low moist places: in some of the streets by the water-side in the city, for instance. The friend to whom I lately alluded lived at Newmarket, a most exposed and bleak spot. But if he left it, and attempted to sleep in a strange place, he never was certain that he should not be assailed in the night by his well-known enemy. So that there were towns in which, after experiencing the effect of their atmosphere, he dared not sleep; and there were others in which he knew he might go to bed in security. It would have been difficult, I believe, to point out any essential difference between some of those localities. His lungs, however, formed an infallible eudiometer. Another college acquaintance of mine, much tormented by asthma, is equally sensible to these inscrutable influences. Two inns in Cambridge are named respectively the Red Lion, and the Eagle. He can sleep in one of them, and not in the other. Nay, he is thus variously affected

within much narrower limits. He assures me that, when in Paris, he never escapes a fit of asthma when he attempts to sleep in the back part of Meurice's Hotel, and never suffers when he sleeps in a front room. Dover Street suits him; Clarges Street does not. He cannot rest in Manchester Square. This he attributes to its being built upon piles. Whether it really has such a foundation I do not know. And agencies still more slight and subtle are enough to set the springs of these seizures in motion. The mere absence of light, for instance. Laennec tells of a man who invariably was roused from his sleep by a paroxysm of asthma, if his lamp were extinguished; or if his chamber-door were shut. The consciousness that the customary preventive remedy was not at hand, has, apparently, sufficed to bring on a fit.

There are many persons who never fail to become asthmatic if they inhale certain effluvia. Particles of ipecacuan floating in the atmosphere, or (what is perhaps the same thing) its mere odour, are insupportable to many. They are thrown into a paroxysm of dyspnœa if they enter an apartment where that drug is under preparation. I think I mentioned before a certain laboratory-man at St. Bartholomew's Hospital who possessed this peculiar and inopportune susceptibility: he was obliged to fly the place whenever ipecacuan was about. Most persons, probably, who have had much experience in druggists' shops, are acquainted with similar examples: so that the influence of ipecacuan in exciting fits of difficult breathing, resembling asthma, is undoubted, and common to many constitutions. We might as well speak of ipecacuan asthma, as of hay asthma, which is a precisely analogous affection. Dr. Marshall Hall calls attention to the familiar but interesting fact, that the same drug, ipecacuan, acting upon the *gastric* branches of the par vagum, excites the reflex spasmodic act of vomiting.

I have said, that the relief afforded by antispasmodic remedies affords presumptive evidence of the spasmodic nature of these attacks. If asthma supervene upon manifested bronchitis, or if there be any signs of congestion about the head, it may be prudent to abstract blood: but this measure will not in general be requisite; and when not requisite, it should be avoided: for whatever tends to debilitate the patient, or to lower his vital powers, tends, at the same time, to augment his susceptibility to the exciting causes of the disease. The dyspnœa may frequently be moderated or altogether assuaged by some form of narcotic. Now opium is the narcotic to which we most trust for the mitigation of spasm in general: and opium is of vast service in paroxysms of asthma. But there is also another of the vegetable narcotic substances which has obtained an especial repute for its effect in quieting the difficult breathing in these cases; and that is *stramonium*. This herb, the *Datura stramonium*, and another species of the same genus, the *Datura ferox*, had long been employed in India as a remedy for asthma. And when it was introduced into this country, about the beginning of the present century, it was cried up as a specific; and everybody who called himself asthmatic began to smoke stramonium: for that is the way in which it has been chiefly employed. The leaves and stalks are cut and put into a pipe, and smoked like tobacco. Stramonium cigars, too, are fabricated. The smoke descends, of course, into the lungs: and when the saliva is swallowed, the remedy is introduced into the system in that way also.

Stramonium thus used, sometimes fails altogether: sometimes calms the paroxysms like a charm. The late Dr. Babington told me of a patient of his who had been grievously harassed for a series of years, by asthma, but who declared to him, after he had made a fair trial of stramonium, that he no longer "cared a fig" for his asthma; which he could always stop in a moment. So a Mr. Sills, in a collection of communications relative to the *Datura stramonium*, published in London in 1811, states, that he had been a great sufferer from asthma: that the fits usually continued, with short interruptions, from thirty-six hours to three days and nights successively; during which time, he had often, in the seeming agonies of death, given himself over, and even wished for that termination of his miseries. But having at length discovered the virtues of stramonium, he uses this strong language:—"In truth, the asthma is destroyed. I never experienced any ill effects whatever from the use of the remedy; and I would rather be without life than without stramonium."

This, then, is an expedient which it will always be well to suggest, for relieving the urgent distress of the paroxysm of asthma. But most patients subject to that complaint, try it of their own accord. We have still to learn why it is so efficacious

in some cases, and so entirely useless, or even hurtful, in others. This probably depends something on the presence or absence of organic disease in the lungs or heart; but more accurate observations are wanted on this point.

Some of the animals upon whose lungs Dr. Williams performed his experiments had been killed by poison. In two instances stramonium was the poison employed; and it is interesting to know that scarcely any contraction of the air tubes could be produced by the galvanic apparatus. The trachea, at the same time, was lax. It is requisite to notice the condition of the windpipe in these experiments; for the same want of contractility would be *apparent*, supposing the parts to be already in a state of tonic spasm, from the operation of the poison. This seems to have been the case when conium was used: the fluid in the glass tube indicated scarcely any compression of the air contained in the lungs; but then the windpipe was so far contracted, that the extremities of its rings met. There was but little contractility, and a lax trachea, after death by belladonna; and after death by the meconate of morphia. The contractility was slight when life had been destroyed by strychnia; but the condition of the trachea is not reported.

Experiments of this kind appear to be well worthy of careful repetition.

It has been suggested, as one clue towards determining the particular kind of case to which the stramonium is applicable, that it succeeds when it causes *expectoration*; and not otherwise. But I doubt about this. The relief is sometimes too sudden to admit of its being so explained. Sir John Forbes quotes the following passage of a letter from an old and intelligent asthmatic to himself. "Smoking tobacco or stramonium is sure to give relief, if it produce expectoration; and it will generally do so if, the moment I awake (*i. e.* in the incipient paroxysm), I begin to smoke, and continue to do so for three or four hours. Smoking, I am able to say, after fifteen years' practice, and suffering as much as mortal can suffer and not die, is the best remedy for asthma *if it can be relieved by expectoration*. I have been in the hands of all the doctors of the place for fifteen years; and still I say, *smoke*."

Of calming vapours thus applied by inhalation to the very parts affected—and operating either immediately upon the nervous fibrils there distributed, or mediately after admission into the blood—the vapour of chloroform is likely, in respect of its soothing power, to supersede all others. Inspired in moderate quantity, far less than is requisite to produce general insensibility, it has already been found of singular efficacy in allaying at once the spasmodic distress of an asthma-fit. But it is likewise manifest already that this is a remedy too potent and subtle to be entrusted to the discretion of the patient himself. We must know more about it than we have yet learned before it can be safely self-prescribed, or self-administered.

Less hazardous certainly, less costly, less difficult therefore of attainment by the many, but less sure also and less rapid in its result, is the respiration of air impregnated with the fumes of burning nitre. The mode of effecting this is simple enough. Pieces of blotting-paper, each as big as one's hand, are to be dipped in a saturated solution of the nitrate of potash—and then dried. One of these papers, being placed on an earthenware plate, and ignited—the fumes presently diffuse themselves throughout the room; and within a quarter of an hour their influence, in many cases, is rendered evident, in "clearing the passages, and gradually opening the air tubes."

The compound spirit of sulphuric æther, Hoffman's anodyne, swallowed into the stomach, is an old and improved remedy. Combined with opium, I have found it of great service in tranquillizing the breathing in asthma. And in one case, which was under my care for some time, I made comparative observations respecting this opiate and stramonium. Both gave much relief; but stramonium the most, and most certainly, *if it were applied in time*. This patient was in the habit of being roused from sleep by the supervention of the paroxysm: and if he had the means of lighting his pipe *instantly*, he could stave the fit off. But when once it had attained its full intensity, he was *unable* to smoke. Under such circumstances, he could swallow the morphia and æther; and the effect of this depended also in a great measure upon the period at which it was taken. It would stop a commencing paroxysm, but had little influence over one that was fully formed. The chloric æther is a more agreeable, but a less potent remedy than the sulphuric.

Of late the lobelia inflata has been much lauded for its beneficial operation upon dyspnoea of all kinds, and upon asthma in particular. I believe its virtues have been

overrated. It sometimes, like stramonium, has an almost magical effect; but frequently it fails to do the smallest good; and I know that sober practitioners who have employed it more than I have, have thought that it may occasion dangerous symptoms. Of my own knowledge, I have nothing worth communicating to you of this drug.

Strong coffee is a common domestic remedy for asthma. The friend and schoolfellow already mentioned used to take it in considerable quantities, and, he assured me, with very great benefit. It is a safe, and simple, and grateful remedy, and has numerous testimonies from medical practitioners in its favour. But it is much less sure than the stronger narcotics.

Ipecacuan, which is so frequently the *cause*, has also been recommended for the cure of asthma; and a host of drugs besides, with which I have no intention to weary you. Among the rest, the application of galvanism was once in great vogue. In the only patient who ever tried it under my own eye,—and he insisted upon being galvanised when his fits were quite absent,—the galvanism brought one on immediately.

If we can shorten or mitigate the paroxysms we do our patient a most essential service, and spare him a great deal of suffering. And during the intervals between the fits, we must endeavour to prevent their recurrence.

For this purpose, I can only just hint at the principle on which we should go. In the simple form of the complaint, when it is apparently uncomplicated with organic disease, we must caution the patient against whatever has a tendency to disturb his general health. He must be temperate in all things; he must be careful in regulating his digestive organs; he must set himself to discover what localities suit him best; and avoid those which experience has shown to disagree with him. And if any one remedial measure be likely to fortify him against his malady, I believe that measure will oftenest be found in the shower-bath, employed in the way which I formerly recommended.

When the familiar preliminary feelings have threatened an attack of asthma, I have often, I think, prevented its accession by causing the patient, just before he addressed himself to sleep, to swallow a pill containing a quarter of a grain, or half a grain, of the extract of stramonium.

If the asthma occur in connexion with any obvious pulmonary or cardiac disease, we must, in addition to the means I have now been adverting to, apply ourselves to the mitigation of such superadded disease. And in respect to this I have nothing more to offer.

I go next to the morbid conditions of the *œsophagus*, so far as they concern the physician; and these morbid conditions are not many. The *œsophagus* lies partly in the chest, and partly in the belly, and therefore may very properly close the subject of thoracic diseases, and introduce those of the abdomen.

The *œsophagus* is less liable to disease than any other part perhaps of the alimentary canal. It differs somewhat in structure (as you know) from all other parts. Its mucous membrane is provided with a thick epithelium, which extends a little beyond the cardiac orifice of the stomach. Beneath lie a dense web of areolar tissue, and two layers of muscular fibres; the one layer being disposed circularly around the tube—the other longitudinally, in the direction of its axis. In some cases there are pouches found in the sides of the *œsophagus*, formed apparently by a kind of hernia of the mucous membrane, between the separated fibres of the muscular coat. These are not common, however, and scarcely worth mentioning, except that their existence has been supposed to have a possible connexion with a curious phenomenon, peculiar to some persons; the power, viz., of *ruminating*; the power of bringing into the mouth again, by a voluntary effort, food which has been for some time swallowed, as cows, and the rest of the *ruminantia* do. There are but few individuals of the human species who possess this faculty; there are but few who have appendices to their *œsophagus*. Whether the phenomenon in question belongs to these last few has never been determined; but as the possible connexion of the two circumstances has been suggested, it is well for you to be aware of it, that you may refute or verify the notion, in case you ever have the fortune to examine the dead body of a person who had the power of ruminating.¹

¹ An instance of the concurrence of a large pouch in the *œsophagus*, with frequent regurgitation of undigested food, has recently (1847) been detailed, in the 30th volume of the *Medico-Chirurgical Transactions*, by Mr. Worthington of Lowestoft: who refers to another example of a like combination, recorded by Mr. Ludlow, of Bristol, in the 3d volume of the *Medical Observations and Inquiries*.

The covering of cuticle protects the œsophagus from the injurious influence of matters passing over it, which might otherwise be hurtful. The morbid state for which we are most often consulted is stricture, *actual* or *spasmodic*. I believe that the œsophagus is very little subject to inflammation, except from mechanical violence or chemical injury. I have seen a few cases, however, in which I inferred a spontaneous inflammatory condition of the tube, from the symptoms complained of; which were a sense of heat and pricking exactly in the course of the œsophagus, felt between the shoulders, and in front precisely in that track (the patients said), where a potato, swallowed too hot, gives pain while it is descending into the stomach. With these symptoms there was some degree of dysphagia, not explained by any thing visible in the throat or pharynx; and some degree of fever. In all the instances of this kind that I have met with, the symptoms have yielded in a few days to abstinence, purgatives, and the application of leeches along the track of the œsophagus.

This part of the alimentary canal often suffers severe injury from the deglutition of certain poisons, especially the corrosive poisons; the strong mineral acids, for example; or the caustic alkalies. We have, in the museum of the College, some very interesting specimens of the effects of these destructive substances. Sometimes, when the quantity of the poison has been small, and its transit rapid, the cuticular lining alone of the gullet is destroyed. It is shrivelled up, broken into fragments, abraded. At other times, the subjacent textures are affected, and ulceration takes place, which at length heals, and leaves a permanent, and generally a progressive constriction of the œsophagus: and sometimes the whole of the internal membranes slough away, and are discharged in one continuous tube, from the mouth; and yet the patient survives for some time. My colleague, Dr. Wilson, had a case of that kind. The patient, a young woman, swallowed about a table-spoonful of oil of vitriol. A week afterwards, she brought up, during a paroxysm of choking cough, a complete cast of the gullet, with ragged ends; or rather the gullet itself. Some of the muscular fibres of the œsophagus were plainly visible on the outside of this tubular slough, in its recent state. She lived eleven months afterwards, swallowing all that time with difficulty and pain, and subsisting on slops and soft food. Yet at one period she certainly gained flesh. After her death, the channel, as it remained after the injury, was taken out of the body and examined. They are both before you;—the original slough, and the ultimate gullet. The latter was formed by a surface which consisted of an irregular cicatrix. The tube was contracted considerably in the lower two-thirds of its course.

When patients have suffered inflammation and ulceration of the œsophagus from these causes, and do not perish at the time, they are very liable indeed to have their existence abridged by the occurrence of stricture of the gullet, which goes on slowly increasing, until no food can pass it, and then of course the patient dies of starvation. I show you here an œsophagus taken from a man whose case I had opportunities of observing from the beginning. He was under the care of Dr. Macmichael, in the Middlesex Hospital. He was brought there in November, 1830, having swallowed, half an hour before, a solution of the impure carbonate of potass, which had been made for the purpose of cleaning paint, and which he had mistaken for beer. Not more than a table-spoonful passed the fauces, and probably none of the poison reached the stomach. He suffered severely, and was in considerable peril for several days, in consequence of inflammation of the fauces and epiglottis; but this gradually subsided, and he went out apparently well. From what I knew, however, of the result of such cases, I ventured to predict that this man would, sooner or later, come back with stricture of the œsophagus. He had always pointed out a spot about half way down the sternum, where he said the oil of tartar had caused him extreme pain, at the very first, and below which he had not felt it.

Accordingly, I was not surprised to see the poor fellow at the hospital in February, 1834, attending as an out-patient. He came there, he told me, because in eating some soup, he had accidentally swallowed, without chewing it, a piece of carrot, which lodged in its way down, and which it became necessary to push onwards into the stomach by means of a probang. Morsels of food had stuck in the same spot before, and it was the very spot where he felt the effects of the caustic at the time of the accident.

He looked tolerably stout and healthy; but said that, since swallowing the potass, he had never been the man he was before.

He continued to make his appearance, from time to time, at the hospital, with similar symptoms, till the 5th of last December (1836), when he was brought there insensible, and evidently dying. We could obtain no satisfactory account of his recent symptoms. He had the mark of a blister, however, on his left side; and upon closely examining him it was plain that that side was full of fluid. It was perfectly motionless in respiration; it was palpably larger than the right side; it yielded everywhere a dull sound on percussion; and no vesicular breathing whatever could be heard there by the ear. The respiration on the right side was puerile; and the beating of his heart, with a systolic bellows-sound, was audible on the right of the sternum.

Although I was certain that the left pleura was full of liquid of some kind, I did not have the thorax punctured: because, in the first place, he was manifestly *in articulo mortis*, and I thought that his death, which was certain, might be attributed to the operation; and secondly, because he was not dying of *suffocation*. His breathing was not laborious or much distressed; but he was dying of coma, and his extremities were already cold, and his pulse was fluttering. I conjectured that an ulcer of œsophagus had made its way into the pleura, and caused inflammation there. But my conjecture was wrong.

I will mention the main particulars of the examination of the dead body, because the case was, in several respects, an interesting one.

There was a considerable quantity of serous fluid in the meshes of the pia mater, beneath the arachnoid; and there was some liquid of the same kind in the lateral ventricles. No other diseased condition could be detected in the brain. The effusion was sufficient, supposing it to have come on suddenly, to explain the coma.

I had the ribs sawn away on the right side, leaving their cartilages attached to the sternum; and then we saw plainly that the heart and mediastinum were thrust over, about four inches by measurement, beyond the mesial line on the right side. The body was on its back. It was easy to perceive how a pleura thus full of fluid must oppress the lung of the other side, especially when assisted by the force of gravity. The left cavity was distended by a greyish coloured and most offensive fluid, of the consistence of gruel; the pleura pulmonalis was covered by a layer of coagulable lymph; and the lung was flattened against the vertebral column. We could not discover any communication between the cavity of the pleura and the œsophagus or air-tubes.

Fig. 99.

Stricture of the Œsophagus.

About the middle part of the œsophagus there was a distinct stricture, occupying about half an inch of the tube. Through this portion it was impossible to push one's little finger; which elsewhere found a loose and ready passage.

In this case, the man did not die of the stricture; but he would have done so had not another disease carried him off. I do not know why the constriction, after it has once taken place, should go on continually increasing; yet it seems to be so. In his *Surgical Observations* Sir Charles Bell mentions three cases like that just described. In one of them, where soap-lees had been the substance swallowed, death took place by starvation from stricture of the gullet, twenty years afterwards; and Sir C. Bell had no doubt that the stricture had originated in the chemical injury inflicted by the soap-lees.

When the symptoms of stricture come on in these cases, physic can do almost nothing. Surgeons pass bougies into the gullet, and attempt to dilate the strictured portion, or to prevent any further narrowing. But this expedient is usually of temporary benefit only; and the patient dies at last of inanition. His miserable existence may

perhaps be protracted a little, by injecting nutritive enemata into the rectum. Sometimes the œsophagus ulcerates through, and a communication is formed between it and the neighbouring parts.

But the œsophagus, like the urethra, and like the bronchial tubes,—like every canal, indeed, in the living body that is surrounded by circular muscular fibres,—is liable to temporary constriction and closure, by the spasmodic action of its own muscles; and this affection is, of course, a far less formidable one than the last.

Patients who are subject to spasmodic stricture of the œsophagus experience occasionally, in some point or other of that tube, a sensation as if there were a knot; or sometimes a feeling as if some solid substance were ascending from the stomach towards the pharynx. If they happen to be then engaged in eating, the morsels of food, after mastication, readily pass the pharynx: but, at a certain distance down the gullet, they stop, and occasion pain, which is felt between the shoulders, or distinctly in the passage itself. Great anxiety and distress accompany this stoppage: and the food is often ejected by a reversed action of the œsophagus.

The symptoms, in fact, are identical with those which result from permanent stricture of the gullet, except that *they* are *not* permanent. When the stricture is organic and abiding, the symptoms occur during or after every meal. When it is simply spasmodic, they come and go, capriciously, we often cannot conjecture why or wherefore, after the fashion of other spasmodic ailments.

Spasmodic stricture may be independent of any disease of structure in any part of the body; but it is of some importance to be aware that it may also be symptomatic of very serious organic changes. Mr. Mayo relates the case of a young man “who had difficulty of swallowing; he could get down liquid food only; and that not without an effort. A bougie being introduced, some resistance was found at the upper opening of the œsophagus, but it yielded; the resistance was spasmodic, and depended upon neighbouring irritation caused by ulceration in the interior of the larynx. The use of the bougie for a few days, with appropriate remedies to the larynx, removed the dysphagia.”

The purely spasmodic cases occur principally in persons of a moveable constitution; in young women whose uterine functions are deranged, and who are liable to hysteria. The remedies for hysteria will prove remedies for the spasm of the œsophagus also. And whatever is calculated to excite ordinary hysterical symptoms, whatever tends to render the system weak and irritable, will tend to aggravate the œsophageal stricture. I alluded to such cases in a former lecture. I give you another, related by Sir Benjamin Brodie. A lady consulted him, unable to swallow the smallest morsel of solid food; and swallowing liquids not without great difficulty. The symptoms had been coming on upwards of three years. A full-sized œsophagus bougie being introduced, entered the stomach without meeting the slightest impediment. This lady's face was pale and bleached: her feet were œdematous. She had long laboured under internal piles, from which repeated discharges of blood had taken place. Under the use of remedies which relieved the piles and the bleeding, the difficulty of swallowing went away.

It is a singular, and it might, if more frequent, be a puzzling circumstance, that very nearly the same symptoms which occur when the œsophagus is permanently or temporarily constricted, happen also sometimes under a totally opposite condition of that tube; I mean its dilatation into a large, inelastic, inert bag. One remarkable example of this I witnessed, in a woman whom I attended in conjunction with Mr. Mayo, some years ago, in the Middlesex Hospital. The case has been fully described by Mr. Mayo, in the third volume of the *Medical Gazette*; and more briefly in his *Outlines of Pathology*. She was thirty-three years old. She was brought to the hospital in a state of extreme feebleness and emaciation. They who brought her said that for the preceding month she appeared to keep down nothing. What she took as food seemed to her to stop in the gullet; and, after a few minutes, it returned. A large œsophagus bougie passed readily into the stomach. She could swallow liquids more easily than solid food. When she took a small quantity it did not feel to her as if it reached the stomach; and in three or four minutes it was invariably rejected. The vomiting was not preceded by nausea, although in its progress it had the appearance of ordinary retching. She craved for food and drink, and seemed literally starving. The complaint had begun ten years before, during her pregnancy, and had

gradually got worse. The belly was so shrunk that the umbilicus was not more than an inch distant from the spine. There was no enlargement or hardness about the stomach; no particular tenderness on pressure of the epigastrium; nor any uneasiness there. She died, utterly attenuated, sixteen days after her admission.

The stomach was found small, and contracted at its middle to the breadth of an inch and a half. The upper part of the duodenum was but half the ordinary size of the ileum. The œsophagus I show you, turned inside out.

It was enlarged to an extraordinary degree of amplitude, as you perceive. At and near each extremity it was healthy, and of its natural size. Intermediately the lining tunic was thickened and opaque, with numerous depressions in it. The muscular fibres, which appeared to have multiplied with the expansion of the canal, were of their natural colour and thickness.

Here is another preparation: a dilated œsophagus with cancerous degeneration of the cardiac orifice of the stomach. I do not know its history; but the mechanism of such dilatation is intelligible enough. The food, unable to pass out of the gullet into the stomach—or passing slowly and uncertainly—the tube behind it is habitually distended, and loses at length its proper contractility. I saw last summer, in consultation with Mr. Mayo, an old gentleman, of seventy, who, for two years, had experienced difficulty in getting food into his stomach. He would eat a few mouthfuls very well; and, then, of a sudden, the next mouthful, after passing the pharynx, would stop just short of the stomach; and a sensation of swelling would arise in the lower and middle part of the œsophagus; and presently up the mouthful would come again. Sometimes, by waiting quietly a little while, the morsel would go on; sometimes he could wash it forwards by a gulp or two of drink; but if once the food got fairly into the stomach he had no further trouble with it. This gentleman had no discoverable disease of the heart or lungs. He gradually grew worse. At last he began to vomit grumous matters, resembling coffee-grounds, and soon died. He was at some little distance from London at the time, and the body was not (I believe) examined. I have no doubt that he had malignant disease of the cardia; and I think it probable that his œsophagus was dilated. I had a female patient about two years ago in the hospital with very similar symptoms; and her stomach was found to be full of cancerous disorganization. The state of her gullet is not recorded. We are apt, in such cases, to satisfy ourselves with ascertaining the gastric disease, without carefully examining that part of the alimentary canal which lies above.

For maladies like these medicine has no cure. Opiates may give comfort, and promote the euthanasia: and that is all.

[During the period of infancy, the mucous membrane of the œsophagus is not unfrequently the seat of inflammation, of a diphtheritic, follicular, or erythematous character. The disease, however, is not very often detected during the life-time of the patient, in consequence of the symptoms by which it is accompanied being those common to many of the affections of the earlier months of existence. In fact, almost the only symptom in many cases of œsophagitis in the infant is frequent vomiting;—immediately after the deglutition of drinks, or of aliments of any kind, these are discharged by vomiting, without having undergone any change. The infant usually refuses the breast and fluids generally, evidently from the pain excited by the act of deglutition; occasionally, however, he will swallow, without much difficulty, half solid aliment when given in small quantities at a time. If the stomach be affected with inflammation at the same time with the œsophagus, the undigested food and drinks discharged by vomiting will be, occasionally, mixed with the morbid secretions of that organ. The disease is seldom attended by any degree of febrile excitement.—The infant is, usually, fretful and restless, and becomes rapidly emaciated. Whenever an infant rejects the breast, or any species of fluid aliment, vomits frequently, and discharges whatever he swallows in the same state nearly as when it was taken, it is the duty of the practitioner to institute a minute examination, in order that he may detect the inflammation of the œsophagus if it exists. It is probable that pressure along the whole track of the œsophagus will excite the cries of the child, when we can have no hesitation as to the diagnosis. If this does not happen, we may nevertheless be tolerably certain as to the existence of the inflammation, if the infant be labouring at the time, or has very recently been labouring, under one or other of the forms of stomatitis. If the

inflammation is confined entirely to the mucous membrane of the gullet, and is not aggravated by improper food or drinks, it will often subside, after a few days, spontaneously; but when it is connected, as is very generally the case, with inflammation of the stomach or intestines, it is an affection difficult to control, and usually fatal. In perhaps the majority of cases, œsophagitis in the infant is preceded by erythematic, diphtheritic, or follicular stomatitis.

The frequency with which inflammation attacks the mucous membrane of the œsophagus in the infant, is evidently due to the predisposition which exists, at this period, to disease of all the mucous surfaces from their constant state of hyperæmia. It is liable to be excited by too much or improper food, or that which is too hot or stimulating. In infants confined to the breast, it may be occasioned by the bad quality of the mother's milk, or by some temporary morbid change occurring in the latter—and which may result from a variety of causes. Œsophagitis has been known to result from the reprehensible nursery practice of administering to infants infusions of spices, or even gin and water, for the purpose of expelling wind, or to relieve the colicky pains with which they are so frequently affected. — In common with all the affections of the mucous membrane in early life, inflammation of the œsophagus occurs most frequently, and is the most difficult to manage in infants exposed to the baneful influence of personal and domestic filth, and a confined and impure air.

The pathological changes detected after death in cases of œsophagitis, are stated by Billard to be vivid redness, with destruction of the epithelium, of some portion of the mucous membrane of the œsophagus, especially of its upper portion; in some cases, a curdlike exudation, more or less extensively diffused, is present; in others follicular ulcerations; a separation of portions of the epithelium, often in large shreds, is occasionally met with; numerous red or dark-coloured striæ occurring where the epithelium is not destroyed; large, irregular eschars of a black colour, with intervals of deep, bright-red excoriations, are occasionally met with, and, in some cases, gelatinous softening of nearly the entire thickness of the œsophagus.

When an infant is affected with œsophagitis, it should not be allowed to take any stimulating or hot drinks—it will be proper, however, to supply it, at short intervals, with a small quantity of some perfectly bland mucilaginous fluid, as gum water, or an infusion of the pith of sassafras, or of the inner bark of the slippery elm, given cold; the throat should be covered externally with a soft, emollient poultice, especially when the inflammation of the œsophagus has succeeded to stomatitis; a few grains of calomel may also be administered, and followed by injections of milk with the addition of sugar. If it be found necessary, the strength of the infant may be supported by injections of milk and broth, or milk with rice flour, tapioca or arrow root. We have derived advantage in cases presenting the symptoms of œsophagitis, from a few leeches applied along the sides of the neck, and internally a teaspoonful, every three hours, of a solution of four grains of the acetate of lead in one ounce of water, with the addition of a few drops of strong vinegar. — C.]

LECTURE LXV.

Diseases of the Abdomen; sometimes difficult to identify. Method of investigating these diseases; by the eye, the hand, the ear. Inflammation of the Peritoneum; its symptoms; and causes. Puerperal Peritonitis. Peritonitis from Perforation.

I AM about to consider the diseases of the abdomen. The organs contained in this cavity of the body are not vital organs in the same sense in which the brain, the heart, and the lungs, are vital. That is to say, the *functions* of the abdominal viscera will bear to be suspended for some considerable time, without the extinguishment of life. But these parts are subject to numerous diseases, some of which are apt to be quickly fatal, and others carry with them a vast amount, and very severe kinds, of suffering.

The parietes of the fore-part of the belly being soft and flexible, you might naturally suppose that the physical morbid conditions of the organs they cover would submit themselves to an easy diagnosis; that the sense of touch, exercised through these yielding walls, would detect alterations of bulk, of form, or of place, in the subjacent viscera, with much facility and exactness. But the truth is, that since the discovery of the method of auscultation, the diseases of the abdomen are much more hard to discriminate than the diseases of the thorax. The reason of this is to be found in the number and complexity of the parts contained in the abdomen; the loose manner in which some of them are packed; and the consequent readiness with which they pass out of their proper and natural situations. It is necessary that I should say a few words, but I shall not detain you long, respecting the *mode of examining* the abdomen, with the purpose of investigating its diseases.

In the description of symptoms, we are often obliged to speak of particular portions of the abdomen: and it will be of future convenience to us if we make ourselves acquainted, at starting, with such a superficial map, marking out the topography of the belly, as I exhibited to you some time since, in reference to the chest. Draw a horizontal line round the body, touching the extremity of the ensiform cartilage; and this will form the superior boundary of the abdomen, thus roughly defined for practical purposes. Draw another such line round the body, horizontally, touching the lower edge of the last false ribs: and a third touching the crest of each ilium. We then have three horizontal zones formed. These must be further divided by vertical lines: one on each side from the anterior spinous process of the ilium perpendicularly upwards. Each zone will thus be subdivided into three regions. The middle region of the upper zone is the *epigastric* region; on either side are the *hypochondria*. The middle region of the middle zone is the *umbilical* region; the *iliac* regions or the *flanks* lie to the right and left of it. The *hypogastric* region is the middle region of the lowermost zone; and the *inguinal* regions are contiguous to it. This is all the division which is necessary.

Now, independently of the *general* signs of disease that have their seat in the abdomen, we are greatly assisted in many cases by the *physical* signs. I shall take a very brief survey of the modes by which these physical signs are collected. They are derived from the exercise of the three senses of sight, of touch, and of hearing.

The sense of sight supplies, occasionally, very valuable information; and in all serious and equivocal cases we must not dispense with its use. We are not, indeed, to make an ocular inspection of the *naked* abdomen *unnecessarily*: and I hold it superfluous to admonish you that when we *do* avail ourselves of that mode of investigation, especially in the case of females, we are bound to do so with the most careful attention not to offend the patient's delicacy. We may sometimes ascertain all that is required concerning the *movements, size, and shape* of the abdomen, without removing the under garments.

This rule applies, indeed, to all parts of the body that are ordinarily covered by the dress.

I was lately consulted by a lady, who told me she had, on the rear of her person, a painful boil. She thought any physician ought to be competent to prescribe for a boil, without wanting to see it. But she seemed very ill, and her sister told me that the boil had lasted a fortnight, and was a very large one; so that I was obliged to press for an inspection. And I found—a boil sure enough, but of that gigantic and formidable species which we call *carbuncle*.

M. Rostan relates a case still more in point. Going round the wards of his hospital, he came to an old woman, who was complaining of a severe pain in the abdomen, towards the left iliac region. Her face was flushed, her skin hot, her pulse strong and frequent, her tongue dry; and she was very thirsty. The abdominal pain was exacerbated by pressure, and by the movements of the patient. Upon these data, Rostan founded his diagnosis. He concluded that the case was one of acute abdominal inflammation; and he prescribed accordingly; and with befitting energy. One of the pupils, however, lingered behind him: and having removed the woman's chemise, in order to examine the seat of pain, he discovered that all the symptoms proceeded in reality from a very harmless, though troublesome, disorder, *herpes zoster*; what is vulgarly called *the shingles*.

Vestis adempta est,
Quâ positâ, nudo patuit cum corpore crimen.

In the second place, we gather very important intelligence by the sense of *touch*. We learn the existence and the size of *tumours*; we approximate to a knowledge of their quality, whether it be solid or fluid; we determine whether they are moveable or fixed, painful or indolent, hard or soft, smooth or uneven, pulsating or not. We ascertain whether the surface be hot or cold. In order to make palpation most effectual, the patient should be placed in the most favourable posture for its performance, *i. e.* he should lie on his back, with his head a little raised by a pillow, and with his knees up. In this position, the abdominal muscles are relaxed and unstrung: and the patient is to be cautioned not to do anything which may make them tense. Sometimes, in spite of this caution, and in spite, probably, of the patient's endeavours to obey it, the recti muscles remain so tightly contracted as to prevent any satisfactory examination of the parts beneath them. The very occurrence of this instinctive striving against the pressure of our hand may be taken as a ground of suspicion that those parts are not in a healthy state. We must take care, when the muscles are thus obstinately rigid, not to mistake the swelling central portions of the recti, or their well-defined edges, for tumours, or for indications of an enlarged stomach or liver. By a peculiar management of the palpation, we often satisfy ourselves at once of the presence of liquid in the cavity of the peritoneum, or in a cyst: we obtain that sensation which we call *fluctuation*.

The exploration by the sense of touch is very much aided—often confirmed, sometimes corrected—by evidence which addresses itself to the sense of hearing. Sometimes we listen to the natural sounds through a stethoscope: and we may thus decide the important question, whether a pulsating tumour be or be not an aneurism; or the question, sometimes scarcely less important, whether or no a different kind of tumour encloses another living being. But, for the most part, our information respecting the maladies of the abdomen, collected by the sense of hearing, is obtained by listening to sounds which we ourselves produce; in one word, by *percussion*: and mediate percussion, percussion performed through the finger as a ready pleximeter, is *particularly* applicable to the disorders of the abdomen. By this expedient we can tell whereabouts the intestines lie; whether the parts beneath the place percussed be hollow and filled with air, or solid; or, though naturally hollow, distended with liquid. By making the patient change his posture, we are enabled often, through the aid of percussion, to trace fluid effusions hither and thither, when they have changed their relative situation in obedience to the force of gravity; and then we know that they occupy the cavity of the peritoneum. All these points I pass over cursorily, because I must advert to them again when speaking of particular diseases. And I shall proceed, on that account, without further delay, to the consideration of those special diseases.

Consulting your convenience, and my own, rather than any scientific order, I shall take, in succession, the several parts and organs contained in the cavity of the belly, and inquire separately into their diseases; inflammatory, organic, and functional. And I begin with the *peritoneum*; the great serous sac which lines and constitutes the cavity of the abdomen, and in which most of its viscera are wholly or partially folded.

Like the serous membranes in general, the peritoneum is very *ready* to take on inflammation, upon the operation of certain exciting causes. Acute inflammation, beginning in one spot, is almost sure to transfer itself to any other spot that happens to lie in contact with the first; and is very apt to extend itself rapidly to the whole membrane. The inflammation tends to the effusion of serum, and of coagulable lymph; it is of the adhesive kind: and its effects are those of distending the peritoneal cavity with fluid—or of gluing its opposite surfaces together so as to obliterate that cavity—or of forming *partial* attachments. In all these respects, the analogy between inflammation of the peritoneum and inflammation of the serous membranes of the thorax—the pleura, and the pericardium—is perfect: and therefore these are points which I shall not dwell upon, except where specific differences arise, from original diversities of structure or of function in the parts affected. I may observe at once, that the morbid conditions which are apt to remain *after* peritonitis, are sometimes, like those which follow pericarditis, *inceptive of further disease*: sometimes, like those of the pleuræ, *final*, and limited to their *immediate* influence upon the health and comfort of the individual; or even *protective* against some worse evil.

Acute inflammation of the peritoneum is characterized by pain in the abdomen, in-

creased on pressure, and attended with fever. But as these symptoms are common to almost all the inflammatory conditions of the parts contained in the abdomen, we

FIG. 100.

False membrane of peritonitis. From a specimen in Dr. Gross' cabinet.

must look for more distinctive circumstances. Cullen defines the disease in this manner: "Pyrexia: dolor abdominis, corpore erecto auctus, absque propriis aliarum phlegmasiarum abdominalium signis." He concludes that it is the peritoneum simply that is inflamed, when the specific symptoms that indicate inflammation of particular organs are wanting. It is not inflammation of the liver, for there is no pain of the right hypochondrium in particular, increased by lying on either side, no pain of shoulder, no jaundice, no vomiting perhaps: neither is it inflammation of the bowels or stomach, there is no disturbed function of the alimentary canal to denote such inflammation.

The pain, Cullen says, is increased when the patient sits up. He might have added, that it is increased also by drawing a long breath, by coughing, sneezing, or straining, and by pressure made with the hand upon the belly. All these circumstances resolve themselves into the same obvious principle; viz., that of pressure aggravating the pain of an inflamed membrane. The erect posture throws the weight of the viscera upon the peritoneum, and tends to stretch parts of it. The pain occasioned by pressure is often excessive: the patient cannot bear even the weight of the bed-clothes. Though the pain is, *at first*, sometimes confined to particular spots, yet it generally soon extends over the whole abdomen, and this is a circumstance of some importance as respects the diagnosis. But *before* the inflammation has become universal, while it is yet restricted to particular spots, the pain is often much increased by pressure made on *other* parts of the abdomen. In truth, in a shut sac of that kind you cannot compress any one part without exercising pressure indirectly upon every other part. The patient cannot sit up, nor, usually, lie on his side; but remains always upon his back: in which position you will perceive that the pressure made by the viscera upon the peritoneum is a *minimum*: is the least possible. He draws up his legs too. And he lies *still*: for *movements* cause pressure, and therefore pain. The descent of the diaphragm in inspiration presses also upon the membrane; and the patient not only complains of the pain thus produced, but, in order to avoid it, gets into a way of breathing by means of his ribs only. So that upon *inspection* of the abdomen, it is perceived that, instead of rising and sinking alternately in respiration, it remains motionless. The phenomenon of *thoracic* inspiration is a symptom of peritonitis. The breathing is necessarily shallow in these cases, and less air being admitted at each movement of respiration, the number of those movements is increased therefore: the breathing is quick as well as shallow: there are perhaps forty, or even sixty respirations executed in a minute, instead of eighteen or twenty. When we find a person lying only on his back, with his knees up, breathing in this manner, and complaining of tenderness of the belly on pressure, and feverish withal, we may be tolerably sure (unless that person be a hysterical girl) that the peritoneum is inflamed, whatever else may be the matter.

The pain in peritonitis is generally sharp, cutting, or pricking in its character. And independently of any pressure made from without, or caused by any change of posture, this pain is apt to be much aggravated at intervals. This, when the inflammation is general, is sometimes owing to the passage of flatus along the bowel, partially distending it, and stretching the inflamed membrane; so that here, also, it is *really pressure* which augments the pain.

When you explore the abdomen by pressure, take care not to make the examination *unnecessarily* a source of pain. Press first gently, with the open flat hand; and keep your eyes on the patient's face at the same time. You will perceive by the expression of his features, whether you are hurting him; even before he takes to verbal complaining.

Acute peritonitis generally sets in with well-marked symptoms: sharp rigors, and high fever, with a hard and strong pulse, which very soon becomes frequent, and often becomes feeble, and is sometimes small from the very first. After the disease has continued for a certain time, it is attended with tension and swelling of the belly. The tension and swelling are tympanitic in the earlier stages. You learn this with certainty by mediate percussion. As the disease advances, the enlargement is sometimes occasioned, in part at least, by the effusion of serum: infallible indications of the presence of which may be obtained by the joint employment of the finger and the ear; by palpitation and auscultation; and by noticing the difference, as to the results of percussion, caused by alterations of posture.

When the disease is advancing towards a fatal termination, the abdomen often becomes greatly distended; the pulse is exceedingly frequent and feeble; the countenance (which in all the stages of the disorder is expressive of anxiety) becomes pinched and ghastly; cold sweats ensue; and the patient dies at length by *asthenia*: death beginning at the heart. The mind is often clear to the very last.

Such is the ordinary course of peritonitis. But other symptoms, which I have not mentioned, do sometimes accompany it; arising out of the peculiar circumstances of different cases. Thus sickness and vomiting occur very frequently; and these symptoms are supposed to denote that the peritoneal covering of the stomach is especially implicated: but I question whether this is always a correct inference. When strangury happens, which is not uncommon, that part of the membrane which is reflected over a portion of the bladder is probably involved in the mischief. Inflammation of that part of the peritoneum which lies in the immediate vicinity of the kidneys, may cause, Dr. Abercrombie thinks, suppression of urine.

Peritonitis is apt to arise under the influence of cold, like other internal inflammations; especially when cold combined with moisture is applied, under certain conditions, to the surface of the body. It is occasionally produced by mechanical injuries inflicted upon the abdomen. It often prevails epidemically, and produces great mortality, among parturient women: and there is ground for believing that this form of the disorder is propagable, and often propagated, by contagion. Besides this, a very terrible kind of peritonitis is a frequent result of the extravasation of the contents of the alimentary canal, or of urine, or of bile, into the cavity of the membrane; through apertures that are sometimes made by external violence, but more often are the consequences of the progress of previously-existing disease.

I shall make a few observations in respect to one or two of these points, and but a few.

That awful disorder, *puerperal fever*, is more frequently accompanied with *inflammation of the peritoneum*, than with any other inflammation. This variety of peritonitis necessarily engages the attention of the accoucheur; and it doubtless is more fully considered in the lectures of the Professor of Midwifery than I propose to consider it. Indeed, if you would understand puerperal fever as a whole; its shifting aspects, its single source, and its appropriate management; you must study Dr. Ferguson's masterly and conclusive essay on that subject.

Of forty-four fatal cases of well-marked puerperal fever which fell under the observation of Dr. Robert Lee, and in which the bodies were carefully examined, the *peritoneum and uterine appendages* were found inflamed in thirty-two: *i. e.*, in eight cases out of every eleven. The inflammation commences, no doubt, in the uterine portion of the membrane, and spreads thence over the larger part of its surface. Now this peritoneal inflammation, occurring in women after childbirth, may be accidental and sporadic; or it may prevail in a district epidemically. And a most dreadful and deadly affection it may then become. In either case, the peritonitis may commence a few days, or even a few hours, after parturition. The pain generally begins low in the abdomen, in the situation of the uterus; which may be felt through the abdominal parietes, and is tender on pressure: but soon a universal swelling takes place, and the womb can no longer be distinguished. Cases of this kind arise sometimes, appa-

rently, from cold; and exhibit no peculiar feature. It is just what we might expect when a female, in a state of weakness and irritability, happens to be exposed to the exciting causes of inflammation. In such a state, a less degree of the exciting cause would be sufficient to produce the inflammation: and probably a less degree of inflammation may prove fatal.

But when peritonitis is frequent among women after childbirth in a particular neighbourhood, or in a lying-in-hospital, it is marked by greater depression of the vital powers, and runs a more irregular course. The nervous system suffers, the sensorium is apt to become affected, and the complaint assumes rather the character of typhus fever than of simple inflammation of the peritoneum. And no wonder; since this variety of peritonitis forms part of a disease which, like typhus fever, is a *general* disease, and results from contamination of the blood. This Dr. Ferguson has clearly established. The contamination may originate in the body of the patient herself; the noxious material being supplied by putrid coagula, or portions of placenta, remaining in the uterus. Or some of the products of inflammation may enter the blood-vessels, and constitute the poison. And this it may be difficult, or impossible, to prevent. But, on the other hand, the contamination may arise in the way of *contagion*; this horrible malady may be communicated from one lying-in woman to another by the intervention of a *third person*; and doubtless it is so carried and propagated, in many instances, by midwives and accoucheurs. Now this source of the disorder may be obviated; and therefore it is of the utmost importance that it should be clearly recognized, in order that it may be carefully provided against.

You must know, however, that great differences of opinion have existed, and, I believe, still exist, in respect to the contagious quality of certain forms of puerperal peritonitis; just as great differences exist as to the contagiousness of continued fevers, of cholera, of the plague. There are persons who regard the whole notion of contagion as a mere bugbear: and there are others who embrace in their allegations of contagion many more diseases than can be *proved* to be so caused. The same strong assertions are made, the same kind of eagerness is displayed (the same party-spirit, I had almost said), as mark the strife of ordinary politics. It is our serious duty, however, to inquire what is the truth in this matter: for the safety of the individuals, and the happiness of whole families, may often hang upon our opinions. I must trouble you, therefore, with a few facts that bear closely upon the subject.

We possess some valuable and highly instructive accounts of epidemics of the kind I am alluding to. One by Dr. Gordon, on the epidemic peritonitis after childbirth, which took place at Aberdeen, in the years 1789, 1790. Another by Mr. Hey, on that which happened at Leeds from 1809 to 1812. And a third by the late Dr. Armstrong, on that which was observed in Sunderland and its neighbourhood, in 1813. Dr. Robert Lee has also collected some very interesting facts in reference to the spreading of the peritonitis by contagion. Dr. Gordon had, he affirms, unquestionable proof that the cause of the disease was a specific contagion, and that it did not arise from any noxious constitution of the atmosphere. The disease seized such women only as were visited or delivered by a practitioner, or taken care of by a nurse, who had previously attended patients afflicted with the same disorder. And Dr. Armstrong observed that forty out of the forty-three cases that happened in Sunderland, occurred in the practice of one surgeon and his assistant.

From among other histories—all tending to the same conclusion—brought together by Dr. Lee, I take the following:—

“On the 16th of March, 1831, a medical practitioner, who resides in a populous parish on the outskirts of London, examined the body of a woman who had died a few days after delivery, from inflammation of the peritoneal coat of the uterus. On the morning of the 17th of March (*i.e.*, the *next* morning), he was called to attend a private patient in labour, who was safely delivered on the same day. On the 19th, she was attacked with severe rigors, great disturbance of the cerebral functions, rapid feeble pulse, with acute pain of the hypogastrium, and a peculiar sallow colour of the whole surface of the body. She died on the fourth day after the attack, on the 22d of March; and, between that period and the 6th of April, the same practitioner attended two other patients, both of whom were attacked by the same disease in a malignant form, and fell victims to it. On the 30th of March he bled a young woman who had pleurisy: the wound became inflamed after a few days; erysipelatous red-

ness, and swelling, extended from it up the arm; and in four or five days that patient died of phlebitis."

Mr. Robertson, of Manchester, states the following facts, in a paper in the *Medical Gazette*.—From the 3rd of December, 1830, to the 4th of January, 1831, a midwife attended thirty patients for a public charity. Sixteen of these were attacked with puerperal fever, and they all ultimately died. In the same month, 380 women were delivered by other midwives for that institution; but none of the 380 suffered in the smallest degree. All the sixteen had inflammation of the peritoneal surface of the uterus. So, also, Dr. Robert Lee tells us that, in the last two weeks of September, 1827, five cases came under his observation. All the patients had been attended in labour by the same midwife: and no example of febrile or inflammatory disease of a serious nature occurred during that period among the other patients of the same dispensary, who had been attended by the other midwives belonging to the institution.

Statements of this kind—and they could be largely multiplied—furnish irresistible evidence, that the peritonitis, which prevails epidemically among lying-in women, is of a specific nature, and communicable from one person to another. It is observed, also, to reign as an epidemic especially in *Lying-in Hospitals*, and that it occurs at *irregular intervals*, sometimes leaving them quite exempt from its ravages for *years* together.

Indeed, I believe that these cases of puerperal fever occurring in succession to the same practitioner, are examples of something more than ordinary contagion, operating through the medium of a tainted atmosphere. I believe them to be instances of direct inoculation. Recollect, that the hand of the accoucheur is brought, almost of necessity, into frequent contact with the uterine fluids of the newly-made mother. Recollect,—those among you who have examined the interior of the dead body with your own hands,—recollect, with what tenacity the smell, which is thus contracted, clings to the fingers, in spite even of repeated washings; and, whilst this odour remains, there must remain also the matter that produces it. Recollect how minute a quantity of an animal poison may be sufficient to corrupt the whole mass of blood, and fill the body with loathsome and fatal disease. Illustrations will occur to you in the inoculated smallpox, in hydrophobia, in the viper-bite, in the scratches and punctures of the dissecting-room. Recollect the raw and abraded state of the parts concerned in parturition; the interior of the uterus forming a large wound, and presenting, as Cruveilhier has observed, an exact analogy to the surface of a stump after amputation; the more external soft parts bruised and sore. Bear in mind the remarkable fact, that this contagion does not affect other persons, but only lying-in women. Reflecting upon these facts, you will see too much likelihood in the dreadful suspicion, that the hand which is relied upon for succour in the painful and perilous hour of childbirth, and which is invoked to secure the safety of both mother and child, but especially of the mother, may literally become the innocent cause of her destruction; innocent no longer, however, if, after warning and knowledge of the risk, suitable means are not used to avert a catastrophe so shocking.

I need scarcely point to the practical lesson which these facts inculcate. Whenever puerperal fever is rife, or when a practitioner has attended any one instance of it, he should use most diligent ablution; he should even wash his hands with some disinfecting fluid, a weak solution of chlorine for instance: he should avoid going in the same dress to any other of his midwifery patients: in short, he should take all those precautions which, when the danger is understood, common sense will suggest, against his clothes or his body becoming a vehicle of contagion and death between one patient and another. And this is a duty so solemn and binding, that I have thought it right to bring it distinctly before you.

In these days of ready invention, a glove, I think, might be devised, which should be impervious to fluids, and yet so thin and pliant as not to interfere materially with the delicate sense of touch required in these manipulations. One such glove, if such shall ever be fabricated and adopted, might well be sacrificed to the safety of the mother, in every labour. Should these precautions all prove insufficient, the practitioner is bound, in honour and conscience, to abandon, for a season, his vocation.

All this I have thus taught in these lectures, from the first. Subsequently to their publication, additional evidence to the same purpose has been promulgated, in the

Fifth Annual Report of the Registrar-General; to which I refer, because the collector of that evidence (Mr. Storrs of Doncaster), points out a wider range of danger than I had indicated, and extends his sound admonitory counsel beyond the cases of puerperal peritonitis, or childbed fever. He shows that the mischief does not always *originate* in the practice of midwifery. The infecting virus is liable to be carried, not only from one parturient woman to another, but from various other sources of animal poison; the circumstances of childbirth rendering the mother peculiarly susceptible of such contagion. More than one series of these fatal maladies have been traced back to the attendance of the accoucheur, at the same period, or just before, upon some case of erysipelas, of sloughing sores, of external gangrene, of typhus fever, and even to his recent presence at the examination of some dead body. In the great general Hospital at Vienna, there are three compartments appropriated to lying-in women. Here upwards of 6000 births take place annually. One of these compartments is assigned to the instruction of medical men and midwives: another to the instruction of midwives only. In the former of these two, fatal puerperal fever was so very much more prevalent than in the latter, as to attract the notice and the intervention of the Government. It appeared upon inquiry that the male students busied themselves with the investigations of the dead-house, and the dissecting-room. A regulation was therefore made and enforced, that every student should wash his hands in a solution of chlorine both before and after every examination of the genital organs in the living subject. From that time the excessive mortality from puerperal fever declined, until it became the same in each of the two compartments. I give these facts on the authority of Dr. Routh. The hazards which I have been pointing out are hazards which the practitioner in midwifery, especially in the country, cannot always avoid; but it is most important that he should be aware of them, and should strive to defeat the risk by the most scrupulous observance of every conceivable precaution.

[PUERPERAL FEVER.—A disease which prevails as an epidemic, or as the endemic of particular localities; suddenly making its appearance among a community, prevailing for a shorter or longer period, and as suddenly ceasing, without our knowing why it came or being able to determine the cause of its cessation;—a disease to which all parturient females within the sphere of the epidemic or endemic influence are alike liable—the young as well as the more aged, the strong, the weak; the lady in her well-appointed comfortable lying-in apartment; the poor daughter of toil in her comfortless, miserable garret; she who has passed through a short, natural, favorable labour, as well as the poor, downcast, exhausted parturient, who has just passed through a tedious, difficult, agonizing labour, with a womb strained and bruised, and in a state, already, of incipient inflammation;—a disease which is ushered in by the usual phenomena of fever, which phenomena do not always follow, but most generally precede the indications of local disease. Does it consist simply in inflammation of the peritoneum, or of one, or several, or all of the pelvic viscera? How happens it that these inflammations, if they be the primary and sole cause of the disease, are so rife under a particular epidemic constitution of the atmosphere, requiring no other predisposition than merely the act of parturition, while in the absence of such epidemic influence the uterus may be tried to its utmost by the efforts of childbirth; it may be ruptured, laid open by the Cæsarean section, have the hand inserted into it in the act of turning—it may be inverted, and subjected to the manipulations necessary for its replacement, and yet no inflammation of the organ shall result, or if it does, it will not be accompanied by phenomena in the least resembling those characteristic of true puerperal fever. Let it be also recollected that the latter disease is not confined to the parturient female. That it may, and often does attack the pregnant female, is admitted on all hands.

There is no other mode of explaining this apparent paradox, than by a recognition of the true character of puerperal fever. That it is not a simple inflammation of the pelvic or abdominal viscera, but the effect of a morbid impression made upon the entire organism, causing a general disturbance of its functions, of which the local lesions are merely the result. In short, that it is a true idiopathic fever.

The fact that, in nearly all the fatal cases of puerperal fever in which a *post-mortem* examination has been made, the evidence has been revealed of inflammation of the

womb or its veins, or of the peritoneum, or of several or all of these parts, is assumed as an incontestable proof of the position, that puerperal fever is purely a phlegmasia, and nothing more.

This fact, however, is freely admitted by all those who see in childbed fever something more than a mere local inflammation—who believe that, in one form of the disease at least, it is a true idiopathic fever, the local lesions being the result of, and not themselves constituting the disease.

It appears to us that attention has been too exclusively confined to the indications of inflammation detected after death from puerperal fever, in the pelvic organs and the peritoneum. These are not the only lesions met with in the bodies of those who have been destroyed by the disease. Rokitsansky describes as frequently present a slight reddening, with investment, of the entire track of the intestinal mucous membrane, by a secretion of a thin serous or viscid gelatinous, or more or less purulent character, softening of the mucous and infiltration of the mucous tissues; a dysenteric exudation on the mucous membrane of the colon, resembling that found on the internal surface of the uterus. A similar exudation is also met with on the mucous surfaces of the respiratory, urinary, or œsophageal tracts. The pleura are almost constantly found to contain exudations similar to those met with in the peritoneum; less frequently they are met with in the pericardium. The articulations very commonly exhibit exudations of a fibrinous or purulent character. The dura mater often presents a slight reddening, with a thin, soft exudation. Rokitsansky describes a black softening of the mucous membrane at the fundus of the stomach or of the œsophagus, indicated during life by black vomit, as a frequent occurrence. According to the same authority, the blood exhibits various changes, its fibrinous coagula present a viscid, greenish-white appearance, or the coagula are scanty, gelatinous, and soft. The blood is of a dirty brown red, or chocolate colour, and glutinous, or it is much attenuated, and transudes all the tissues. Vegetations on the valves may form from mere mechanical deposition.

In the dissections made in Philadelphia, during the epidemic of 1842, the liver, spleen, and kidneys were found softened, as in cases of malignant fevers. In one of the cases, the stomach contained a fluid resembling coffee-grounds, and probably the same as the black vomit of yellow fever.

That the disease is not essentially a local inflammation, of which the fever is merely a symptomatic or sympathetic effect, is disproved from its having been found, as remarked by Dr. Simpson, that: "1st. There is no general uniformity of relation and sequence between the degree and intensity of their supposed cause—the local inflammatory lesions—and the degree and intensity of their supposed effect, the attendant fever. 2d. Sometimes the supposed cause—in the form of simple peritonitis, or metritis, &c.—may exist, without these inflammations exciting the usual phenomena of their supposed effect, namely, the symptoms of puerperal fever; and, 3d. We see occasionally cases of true and fatal puerperal fever, without discovering on the dead body any traces or evidence of the local inflammation which had been considered the origin of the disease. In other words, under this last class of cases we have the existence of the supposed effect without the existence of the supposed cause. And this observation holds good with regard not only to the individual local inflammations, which have been illogically dogmatized into the alleged invariable origin of puerperal fever, but it holds good with regard to the whole class of local inflammatory causes. Some authors, while they maintain the disease to be a fever entirely symptomatic of some local inflammation, at the same time hold that this local inflammation may be seated in different parts in different cases, and different epidemics, and that the disease originates, in one case, in metritis, in another, in ovaritis, in a third, in peritonitis, and so on. Without remarking on the illogical nature of imagining that the same disease may have such varied origins, we may, once more, pointedly observe that—as sometimes happens in continued fever—occasionally, though very rarely, no inflammatory lesions whatever can be traced upon the bodies of patients who have died of puerperal fever. Dr. Locock has observed several cases of this kind; and, in the practice of the late Dr. Beilby, I saw one very marked and rapidly fatal case of puerperal fever, in which my colleague, Professor Bennett, was unable to detect anywhere in the abdomen, or in the uterus, its appendages or vessels, any traces of inflammatory action or

effusion. The great rarity of such instances is no sufficient argument against their important bearing upon the question of puerperal fever."

Dr. Meigs, in his recent treatise on childbed fever, repudiates the existence of an idiopathic puerperal fever, inasmuch as the term fever excites "a certain material idea of zymosis in the mind of the hearer of it;" but he, nevertheless, substantially admits all that would be necessary to include puerperal fever in the list of zymotic diseases.

"Childbed fever," he remarks, "becoming epidemical, may prevail so extensively as to implicate almost all the women who are brought to bed under its reign; or the force of the cause may be so slight as to produce illness in only here and there an unfrequent example, so that the epidemic cases may be very rife or not."

And again: "It is quite clear," he says, "that the malady may break out, and rage with violence in certain circumscribed spaces; and on the other hand, that it may prevail, at one and the same time, over extensive districts, and even whole nations and countries, and yet be ever one and the same disorder."

"There are, then," he observes in another place, "atmospheric causes, that render pregnant and lying-in women, at particular times, and in certain places, uncommonly liable to attacks of childbed-fever inflammation. What the real principle of this epidemic is, I believe there is no man can say. Be it what it may, one of the most extraordinary conditions connected with it is this: *that it should not poison men, nor boys, or girls, or non-pregnant women, but only the pregnant or lying-in portions of society.* This appears to me to be its greatest mystery."

Now, is it strictly true, that the atmospheric cause of epidemic puerperal fever, whatever its nature may be, poisons only "the pregnant or lying-in portions of society?" If we examine the histories that have been furnished us of the several epidemics of erysipelas that have prevailed in different portions of the United States, we shall find that a certain morbid condition of the atmosphere may occur, which, while it produces in some of those subjected to its influence an erysipelatous affection of the skin, in others it gives rise to inflammation of the mouth and fauces, or of the lungs and pleura; in others, again, to inflammation of the peritoneum; and, in pregnant and parturient females, to puerperal fever.

Dr. Drake makes the following statement, based upon an analysis of the several accounts given of epidemic erysipelas as it occurred in the Interior Valley of North America:—

"The peritoneum in men and non-parturient women was obnoxious to the inflammation, but not in as high a degree as the pleura. Pregnant, and especially lying-in females were, however, peculiarly liable, and the most fatal cases were the puerperal."

In the terrible epidemic of erysipelas which prevailed near Norristown, Pennsylvania, in the autumn of 1847, "old and young, male and female, fell before it," says Dr. Corson, "and yet there seemed to be one class that it preferred. The mother, as she lay helpless and exhausted from the labour and agony endured in giving birth to her child, was marked as a victim. The deadly poison was infused into her veins, and, in many instances, a few hours sealed her doom." "I lost more puerperal women during the epidemic than for twenty years before." "This epidemic produced in one class of patients well-marked erysipelas, in another inflammation of the mucous membranes lining the fauces and nasal cavities, and in a third, diffused inflammation of the serous tissues; while yet others were met with, in which all these conditions followed each other, or existed simultaneously." "In females, the serous membranes were affected generally, while in males the mucous or cellular tissues were almost the only parts involved."—(*Trans. Pennsylvania State Med. Soc.*, vol. ii.).

In the winter and spring of 1851–52, epidemic erysipelas again made its appearance in the upper portion of Montgomery County, Pa. "The disease," says Dr. Vanbuskirk, "seemed first to attack the throat, and afterwards the surface of the body. In females, it was especially liable to attack the peritoneum, and one or other of the serous tissues in the male. When the peritoneum became affected, there was much hiccough from the disease extending to the diaphragm. In some cases, symptoms of arachnitis, followed by coma, presented themselves." It is further added, that many cases of puerperal fever occurred during the prevalence of erysipelas; and, as far as information was obtained, "these cases of puerperal fever were confined

chiefly to the same localities as the latter disease." — (*Trans. Penn. State Med. Soc.*, vol. ii.).

Speaking of the epidemic erysipelas as it occurred in Montgomery County in 1852, Dr. Geiger informs us that, "it spared neither age, sex, nor condition." "It marked the parturient woman for its especial victim. Not a single woman living within the range of the disease, who was delivered during its prevalence, escaped an attack." "Besides those cases of puerperal fever which were evidently erysipelatosus, males were frequently attacked with symptoms indicating inflammatory disease in one or other of the internal organs, as the brain, lungs, heart, intestines, and their serous investments." — (*Trans. Penn. State Med. Soc.*, vol. iii.).

In the latter part of March, 1852, epidemic erysipelas made its appearance in Palmyra County, Pa. "Few lying-in women," says Dr. Gloniger and Breitenbach, "escaped its attack, and the ratio of mortality, we have been informed, was quite large." — (*Op. citat.*, vol. ii.).

Dr. Bennett, in his history of the epidemic erysipelas which prevailed in Danbury, Connecticut, during the winter and spring of 1847-48, says: "The serous membranes were a frequent seat of the disease, especially the pleura and peritoneum. Three cases of puerperal peritonitis are included in the list." — (*Trans. Amer. Med. Assoc.*, vol. ii.).

Dr. Mendenhall, in his report on the epidemics of Michigan, &c., tells us that "erysipelas has prevailed as an epidemic for the last two years (1851 and 1852), usually affecting the head and face" — "puerperal peritonitis prevailed contemporaneously with erysipelas in this region. In some cases the erysipelas attacked the labia and vagina, and was soon followed by puerperal peritonitis." — (*Trans. Med. Assoc.*, vol. v.).

In 1853, erysipelas prevailed as an epidemic in Dayton, Ohio; Dr. Sutton informs us that females advanced in pregnancy were exceedingly prone to premature labour, and the period of accouchment was looked to by both patient and physician with the deepest anxiety and solicitude. But one parturient female within the range of Dr. Sutton's information escaped an attack of puerperal fever — and every one that was attacked died.

Non-pregnant females suffered in many instances from inflammation of the peritoneum and of the pelvic viscera, and males from inflammation of the respiratory mucous membrane, or of one or other of the serous surfaces. — (*Op. citat.*, vol. v.).

But it is unnecessary to multiply evidence to prove that the same epidemic cause which gives rise to erysipelas may also produce in the male, and in the non-pregnant and non-parturient female, peritoneal inflammation, and in the pregnant and parturient woman the disease termed puerperal fever. Every historian of the epidemics of erysipelas that have occurred of late years, with scarcely a single exception, bears testimony of the fact. The intimate connection between epidemic erysipelas and childbed fever — a connection that had been already recognized by Gordon, Beatty, Nunnely, Kneeland, Holmes, and others — is now, indeed, very generally admitted. Dr. Hutchinson and others have seen both diseases in the same patient. Dr. Simpson, of Edinburgh, has recently advanced the opinion that erysipelas and phlebitis are diseases in "the same category as puerperal fever."

Of the intimate connection between typhous fever, erysipelas, phlebitis, and puerperal fever there can be no doubt.

Much of this, to use the words of Dr. Ormerod, is explicable on the supposition of the existence of the same atmospheric condition affecting all who cannot resist it, in the same way; but however this may be, as far as general impressions, in the absence of notes, will justify the assertion, simultaneous with the occurrence of some cases of fever in the medical wards, phlebitis and troublesome sores are more commonly met with in the surgical wards of this hospital, and erysipelas of the head and face in both.

The force of the facts just referred to, has been attempted to be evaded by a denial of the pathological identity of puerperal fever and erysipelas. But this is a mere play upon words — a mere evasion of the very question at issue. No one ever pretended that the affection of the surface denominated erysipelas, and the collection of morbid phenomena constituting puerperal fever are one and the same disease. Nor is it necessary to prove that the two diseases are identical in all their pathological characters before admitting their production by the same morbid condition of the atmos-

phere. The difficulty in the mind of those who deny the relationship between epidemic erysipelas and childbed fever has originated from the supposition that the epidemic malady, one of the most frequent manifestations of which is an erysipelatous inflammation of some portion of the surface, and the disease known as puerperal fever, are essentially local phlegmasiæ. May we not, with Mr. Nunnely, admit it to be highly probable, if not certain, "that there is," in erysipelas, "some change produced in the state of the blood, which change may depend upon alterations we are unable at present to appreciate, but which, it is likely, occur in many tissues, and may thus affect the mass of blood more or less quickly, and to a greater or less extent, according to the influence they have upon, and the connection they have with, the blood in a state of health."

Dr. Meigs tells us, in his recent treatise, that he is not prepared to say "the epidemic might not have the power over the nervous mass, so to qualify its operations as to determine, in one individual, an inflammatory attack of the corpus mucosum of the skin, and, in another, an attack of inflammation of the serous coat of the belly." But he cannot conceive of a case of pure metritis or metrophlebitis being produced by the same cause as that productive of erysipelas, or possibly of peritonitis.

"Erysipelas," he remarks, "is a disease of the skin, and although, in some instances, it does take on a phlegmonous character, by extending perpendicularly downwards into the connecting areolar texture, it does so only by accident, and not as a normal process of that special phlegmasia. Erysipelas is, therefore, a membranous, but not a viscerous disorder, and one of its chief characteristics is found in its propensity to expand its areas of phlegmasia far and wide over the plane of the membrane. Puerperal peritonitis, pure and simple, is also a membranous disease, and possesses the same propensity to expand its areas over the entire plan of the peritoneal membrane. In this, erysipelas and peritonitis are alike; but erysipelas and metritis are not alike. Peritonitis is also like erysipelas in this, that it has a tendency to plunge or descend vertically in the basement textures of it, and so destroy the epiploon, or gangrene the bowel, or produce ramollescence of the exterior stratum of the uterus, or exo-metritis. In erysipelas, this vertical plunge or down sinking of the morbid states of the corpus mucosum often carries it quite through and below the corium, and far down into the substratum of areolar tissue, where it may become either phlegmonous or oedematous erysipelas, as the case may be.

"In like manner, when you shall hereafter examine the mortal remains of individuals who have died of pure childbed peritonitis, though you shall not, in general, observe any other than the results of a purely membranous inflammation, or inflammation of the peritoneum, yet, in some specimens, you may find the epiploon softened and suppurated, the ovaria reduced to a pulp, or the outer stratum of the womb completely reduced to a state of ramollescence or softening. In so far, then, as I have drawn a parallel between the two disorders, you discern a very great similarity between them."

"Why should you vex yourself with this foolish question, when you are already so well informed in your profession as to know that childbed fever is puerperal peritonitis, and nothing else; and that peritonitis, in numbers of the cases, does not come in question at all, the disorder being pure womb-phlebitis alone, or an oophoritis, &c. &c. If you must insist that erysipelas and childbed fever are one, then pray leave out of question all the pure metrites and phlebitis, and confine your alliance between the two to the serous and dermal identities, if they must be so considered."

We agree with Dr. S. Holmes, in the opinion advanced by him in his recent very able paper on erysipelas, (*Trans. Amer. Med. Assoc.*, vol. vii.) that pathologists have committed an unfortunate error in their efforts to find some one tissue on which the inflammation in erysipelas is expended, while we are convinced that the lesion of several tissues is common, even in the milder forms of the disease. With Dr. Holmes, we hold "that the peritoneum, the pleura, or the arachnoid may take on the erysipelatous inflammation as certainly as the lining membrane of the fauces; if the disease be constitutional, it, like many others, shows preferences to particular parts, but is not confined to those parts; it can no more be called 'a dermal disease' than it can be called a peritoneal disease. In its signs, it is a peculiar form of inflammation, with characters as strong as an inflammation where lymph is thrown out for adhesions, or pus for a covering or protection. Its pathological exudation is like that of many

others, merely a deficiency in its physiological exudation; but, in proportion to the potency of the cause, so will be the power of the exudation to assume the pus formation, or the fibrinous or the simple agglutinative lymph. The pus may show a greater tendency to form on mucous than on serous textures, but that does not exclude the serous, and in proportion to the gravity of the cause will be the result."

We can readily understand, when we consider the condition of the pelvic and most of the abdominal viscera in the female immediately after parturition, why these should be particularly predisposed to the action of the *materies morbi* by which the inflammation in epidemic erysipelas is produced.

Let this be as it may, we have the fact incontrovertibly established that, during the time and in the same place at which erysipelas is prevailing epidemically, males and non-pregnant and non-parturient females are especially liable to suffer from peritoneal inflammation, while pregnant and lying-in women are particularly exposed to an attack of the so-called puerperal fever; and, in the examination of the bodies of those who have died of the latter disease at such periods and places, it is not the peritoneum alone to which the results of inflammation are confined, but the uterus, its veins, its ligaments, the ovaries, and neighbouring intestines are as frequently found involved in disease.

Were this the proper place to enter upon a discussion of the subject, we should have no hesitation to assume as true, and we think we should be able very clearly to demonstrate the actual identity of the pathological character of erysipelas, phlebitis, and puerperal fever. The supposition of the formation of pus in consequence of an inflammation of certain veins, and this pus finding its way into the circulation, giving rise to purulent deposits or secondary abscesses, and the morbid condition known as pyemia, has been shown to be unfounded by Lebert and Rokitsky. The whole of the phenomena in cases of pyemia depend upon a general poisoning of the blood—as the result of which we have local phlebitis—often in several parts of the body widely remote from each other, and true suppuration—the result of circumscribed inflammation within the substance of many of the organs.—It would not be difficult to show that precisely the same dyscrasy of the blood occurs both in erysipelas and in puerperal fever.

The low adynamic form of childbed fever which so generally prevails in over-crowded and ill-ventilated hospitals, is supposed by some to be either purely typhus fever without implication of the generative organs, or a combination of phlegmasia of these with typhus fever. Of the former cases nothing need be said, as it is not to be supposed that any well-instructed physician would confound typhus or typhoid fever with puerperal fever.

Puerperal fever is, confessedly, the especial endemic of the lying-in wards of hospitals, and it there presents itself, usually, in its most malignant and intractable form. Now, when it occurs in these institutions simultaneously with typhus fever, erysipelas, and hospital gangrene, are we to admit the conjoint presence of three distinct morbid states of the atmosphere, the one productive of typhus fever, another of erysipelas, and a third of childbed fever, or subscribe to the opinion of Dr. Walsh, that puerperal fever is not a disorder *sui generis*, confined to lying-in women, but "merely an unusual form of a very common disease," being, "in reality, no other than the common infectious fever, complicated with more or less extensive inflammation of the peritoneum;" and, we would add, the womb and its appendices.

Dr. Meigs would appear to admit that the endemic cause of typhus fevers may give rise to the very lesions in which he considers the so-called puerperal fever to consist.

"I beg of you," he remarks in his late work, "to understand me as asserting that, while childbed fever is a phlegmasia, and that while there is not, in our nosology, such a thing as a true idiopathic childbed fever, I yet admit the possibility of typhus, jail, hospital, and ship fevers occurring in our class of patients." Some of the cases proceeding to their solution, in recovery or death, without interesting in a particular manner the child-bearing organs, or the peritoneum: while there are others that early establish areas of phlogosis, which may or may not take up the mastery in the subsequent progress of the malady."

We can understand the foregoing language, vague and cautious though it be, to imply nothing, more or less, than that the epidemic or endemic cause of typhus fevers is capable of giving rise, in pregnant and parturient females, to puerperal fever. If

it do not mean this, it means nothing. Now, taken in this sense, in connection with the admission that childbed fever may be the result of an atmospheric poison, or some malign condition of the surrounding air — everything is admitted that we contend for — namely, that some general morbid cause — we shall not dispute about its nature, probably this will be forever hidden from us — by its impression upon the nervous system — upon the endangium — or by its gaining an entrance into the blood and modifying its erasis — the question as to its primary mode of action upon the organism being a matter of indifference as to the main fact at issue — so disturbs the general functions of the living body as to give rise to those morbid phenomena, which constitute the disease we call idiopathic fever — one of the consequences of which general disturbance of the functions — under certain circumstances and in certain individuals — is, in addition to various other lesions, inflammation of one, or several, or all, of the pelvic viscera, and of one or other of those of the abdomen.

As Mr. W. Tyler Smith remarks, in his Lectures on Puerperal Fever, published in the *London Lancet*, “The more puerperal fever is investigated and tracked, as it were, to its elements or origin, the less satisfactory does any partial or local explanation of its origin become. In the progress of such an examination, it appears more and more evident that there is a puerperal (febrile) poison to which the lying-in woman is liable, and which produces all the varied phenomena of puerperal fever met with in different epidemics, localities, seasons, and constitutions. In one time or season, peritonitis is produced, in another, metritis, in another, phlebitis, in another, mammary or other abscesses; in another, low fever, in another, intestinal irritation, in another, dissolution of the blood, without a trace of local inflammatory disorder, and so on throughout the list of local and special disorders which have been described by authors on puerperal fever. It may be questioned, even if phlebitis ever occurs without a poisonous condition of the blood, produced either as the result of contagion, epidemic influence, or the absorption of putrid matter from the uterus. Thus, in the earliest pathological arrangements, a great number of disordered states were grouped together as puerperal fever, without attempt at discrimination or analysis; next came a laborious separation of the different forms and manifestations of the disease; and the subject seems, at the present time, ripe for allaying the numerous affections met with in puerperal fever together, in their origin from a common cause — namely, some animal poison, or zymotic influence.”

Under this view of the case, puerperal fever loses the anomalous character which so long has been ascribed to it — it ceases to be a mystery. It is no longer an epidemic disease whose subjects are alone parturient females; but one of the forms of a prevailing epidemic fever; its peculiar features in the recently-delivered woman, not being due to a specific virus to which she alone is liable, but to the condition of the uterus and its appendages immediately after child-birth predisposing them in an especial manner to become the seat of disease, amid that general disturbance created in the living organism by the morbid influence of the prevailing atmospheric poison, the malaria, the epidemic constitution, or whatever other name may be given to the reigning epidemic or endemic cause. But of which, let it be recollected, the influence is not experienced solely by the inmate of the childbed, but is experienced by the community at large, producing, in males and females, a fever accompanied in its course by erysipelatous inflammation of the surface, or by inflammatory affections of the mucous or serous tissues, and often, in the unpregnant female, by nearly all the leading features that characterize it when it occurs in the parturient woman. — See note by the Editor to Churchill on the Diseases of Women, Last American Edition, Philada., 1857. — C.]

The cadaveric venom here referred to, is well known, and is justly dreaded by us all: and especially by those among us who are oftenest engaged in examining the interior structure, whether healthy or diseased, of the dead human body. Admitted through a cut, a puncture, a mere abrasion of the cuticle, it gives rise to ill-conditioned sores, tenderness of the absorbents, diffused inflammation of the reticular tissue, and great constitutional disturbance. Many promising students, many valuable members of our profession, have perished prematurely of this accidental inoculation. There is reason to think that the virus is produced in the early stages only of the process of decomposition: that when putrefaction has reached a certain point, the point at which

sulphuretted hydrogen is evolved, the special poisonous quality ceases. It is during a particular stage of their decay, that German sausages, bacon, and cheese, are sometimes found to acquire deleterious and even fatal properties. The claws of carnivorous beasts, and the beaks and talons of carnivorous birds, are apt to be charged with the same kind of poison; which gives to their bites or scratches a peculiarly dangerous character.

[The connection between puerperal peritonitis—or, to speak more correctly, between *puerperal fever* and erysipelas, has recently attracted a good deal of discussion. The facts in support of such connection are too numerous and too well authenticated to allow of any reasonable doubt being entertained upon the subject. It has been shown that the two diseases prevail very generally simultaneously in the same localities, while one of the most common lesions attendant upon constitutional erysipelas, in the male subject and in non-pregnant females, is peritoneal inflammation. Facts have also been adduced, which prove that a contagion of some kind may be communicated either directly, or through the intermedium of a third party, from a patient laboring under erysipelas to the parturient female, and induce in her an attack of puerperal fever. — C.]

That variety of peritonitis which results from perforation of the stomach or intestines, and the effusion of their contents into the cavity of the belly, is full of interest. The inflammation is violent in degree; universal (generally) in extent; and almost always fatal. The attack is characterized by its *suddenness*. All at once intense pain arises in some region of the abdomen, which soon becomes tender in every part. The pain is incapable of removal, and usually even of mitigation, by medicine, and death takes place in a short time. These are the general features of such cases. Occasionally, the symptoms follow some different order. Thus, I have seen a case in which no pain was complained of, and the source of the inflammation was not suspected until the dead body was examined. This was a case of *fever*; and it had been attended with much stupor, which was probably the reason that no indication of suffering was made by the patient. Occasionally, but that is uncommon, the pain intermits. For the most part, however, it resists all treatment, and ceases only with life, or a short time before life is terminated.

Most of the instances of this kind of peritonitis that I have witnessed, have resulted from perforation of the ileum, in the progress of continued fever. You are already aware, that the glandulæ agminatæ, which are found only in that bowel, and the glandulæ solitariae, which are scattered over nearly the whole inner surface of the alimentary tube, are very liable, in one species of continued fever, to inflammation, sloughing, and ulceration: and sometimes the ulcers *go through*: the contents of the gut are poured into the cavity of the serous membrane, and intense inflammation is lighted up. I purposely abstain from going into any particulars respecting these sloughing ulcers. We are no further concerned with them at present than as they furnish the channel by which the cause of the peritoneal disease is introduced. Once, and once only, as I stated before, have I known perforation occur from the extension of scrofulous ulceration of the same glands in *phthisis*. In general, in that disease, the ulcer runs a much slower course. As it approaches the peritoneum, circumscribed chronic inflammation is set up in that membrane; lymph is thrown out; and the bowel becomes adherent to some other portion of the canal, or to some of the other viscera of the abdomen. In this way the perforation is prevented; or, it should take place, the escape of the contents of the bowel into the peritoneal sac is prevented. Occasionally, when two portions of the tube thus adhere together, a communication is formed between *them*, and the contents of the intestine either reach an advanced point of their stated journey by a short cut; or are carried back again perhaps to a spot which they had already passed.

A very singular instance of this latter event has been described by Dr. Abercrombie. A man, fifty-six years old, who had shown no signs of serious illness, but had laboured under impaired appetite, languor, and occasional pain in the abdomen, for two or three weeks, was suddenly seized, while taking a walk, with vomiting; and he observed that what he brought up was stercoraceous; and this occurred again and again, at various intervals; the matter vomited being distinctly fecal, and sometimes

so solid that he was obliged to swallow warm water to soften it, that it might be expelled from the stomach more easily. He never vomited his *food*: and no tumour, nor any other sign of organic disease, could be detected by external examination. He lived about three months, and died at last of exhaustion; and then it was discovered that the stomach and the transverse arch of the colon were adherent to each other, and that a ragged aperture of communication between them existed at the place of adhesion.

I have learned of late, from Dr. Brinton, whose attention has been specially directed to this subject, that there are on record at least twenty cases of a communication, thus formed by adhesion and ulceration, between the stomach and the colon.

It is a curious fact, that the vermiform appendage of the cæcum is not unfrequently the seat of a penetrating ulcer. I have traced little groups of glands in that slender tube: and I have known perforation to happen from the specific ulceration of typhoid fever; and from the accidental ulceration caused by a cherry-stone lodged there in one instance, and by a pellet of hard faecal matter in another.

Sometimes it is the *stomach* that is perforated, either by a common or by a specific ulcer; and the symptoms are exactly the same as when the *bowel* gives way. Sudden, unremitting pain; tenderness, and tympanitic distension of the abdomen; and early death.

Perforating ulcers of the stomach are of various kinds. It is not uncommon to find one small roundish hole, somewhat larger generally on the inner than on the outer surface, the edge of the mucous membrane being as smooth and clean as if a disk had been cut out from it by a punch, and without any surrounding hardness, or other mark of disease. Occasionally the orifice is more irregular, and occupies the centre of a thickened and indurated patch of the mucous membrane. Several instances of this sort of perforation have occurred under my own eye; two within the last fourteen months (1839). Almost all the patients have been young unmarried women, plump, and in good condition; who, up to the moment of the fatal seizure, either seemed to enjoy perfect health, or, at most, had complained of slight and vague feelings of dyspepsia. Ulcers of the stomach are, however, mostly chronic; and the diseased viscus is commonly fenced about and protected by adhesion to the neighbouring parts, before its coats are completely penetrated by the ulcer. You are probably aware that this happened in the body of Napoleon Bonaparte. He died of cancer of the stomach. That organ was strongly adherent to the concave surface of the left lobe of the liver, which formed a part of the wall of the stomach; and this adhesion, no doubt, prolonged his life.

The actual perforation, in cases such as we are now considering, may result merely from the natural progress of the ulcer; but sometimes it would appear that the thin membrane which remains is broken by some accidental force applied to it. Thus the distinctive symptoms occur most frequently after a meal, when the stomach is distended with food, and engaged in the churning movement which attends the process of digestion. They have immediately followed the act of vomiting, brought on by an emetic. Bouillaud relates an instance in which the perforation happened while the patient was straining at stool; and it is conceivable enough, that rough pressure of the abdomen might complete the rupture, when the ulcer had already eaten through all the coats of the bowel except its peritoneal coat. I shall return to this subject in a future lecture.

Occasionally the perforating ulcer has its seat in the *duodenum*. And it is a very curious fact, of which no satisfactory explanation has hitherto been given, that ulcers in the duodenum, at no great distance usually from the pylorus, are of common occurrence in persons who have suffered severe and extensive burns. A number of cases of this kind have been published by Mr. Curling in the 25th volume of the *Medico-Chirurgical Transactions*. The inflammation and ulceration probably commenced in one or more of the glands of Brunner. Frequently the ulcer leads to adhesion between the gut and the pancreas. Sometimes it penetrates into the abdominal cavity, and excites fatal peritonitis.

Less commonly than this, in my experience at least, the peritonitis is set up by the escape of urine from the *urinary bladder*, through the extension of an ulcer, or from the forcible rupture of that bag by a blow or a fall, when it was distended with urine. Rupture of the *gall-bladder*, whether by violence or from ulceration, has the same

results; so also has, in general, the rupture of the *uterus*, which sometimes takes place during the efforts of parturition. *Abscess of the liver*, bursting into the peritoneum, is another occasional source of severe and fatal inflammation of that membrane. Acute and general peritonitis sometimes arises, also, in consequence of penetration from without; *i. e.*, it succeeds the puncture made by the trocar in the operation of tapping the belly: and these cases too, are almost all of them mortal; chiefly, I presume, because, in nine instances out of ten, they occur in an unhealthy and debilitated subject.

I formerly offered you some observations respecting a form of hysteria which very closely *mimics* peritonitis, and would most certainly deceive a medical man who was not on his guard against it. We judge by the age and sex of the patient somewhat; by the presence of hysteria in other forms, or of the hysteric diathesis; by the *excessive* tenderness of the abdomen, or rather of its surface; by the coexistence of the same exquisite sensibility in other parts; and by the incongruity and shifting character of the symptoms. The pulse and the tongue will perhaps be natural, while the abdominal irritation is at its height. Forewarned, you will seldom find much difficulty in establishing the diagnosis. Of the signs by which peritonitis may be distinguished from enteritis, I shall speak when I come to the latter disease.

LECTURE LXVI.

Treatment of Acute Peritonitis; Bleeding, Mercury, Opium. Chronic Peritonitis. Granular Peritoneum. Ascites; Ovarian Dropsy; Diagnosis of these diseases. Other forms of Abdominal Dropsy.

ACUTE peritonitis, in its simple form, is always a dangerous, yet frequently a manageable disease. When it is complicated with other and earlier organic mischief, and especially when it has been excited by the entrance of foreign matters into the cavity of the belly, it is all but hopeless under any treatment.

In speaking of the mode of cure, I have again to rehearse, *mutatis mutandis*, the grand remedies for inflammation, and particularly for the adhesive inflammation proper to serous membranes: *blood-letting; mercury.*

It is of the greatest importance in this, as indeed in all cases of inflammation, that the blood-letting should be performed *early*. You must not be deterred from bleeding by the mere smallness of the pulse: a quality which I have frequently shown you to be characteristic of acute inflammation within the abdomen; and which, in the disease now in question, is often present from the very beginning. If the pulse be wiry and hard, we disregard, in these cases, its smallness. Not uncommonly it is rendered more full, as well as softer, by venæsection; and this when it happens, gives assurance of the propriety of that measure.

Topical blood-letting is of much efficacy—of greater efficacy perhaps than in most other forms of abdominal inflammation. Cupping is out of the question, from the tender state of the abdomen. But in adults, after a full bleeding from the arm, such as has produced some sensible impression upon the circulation, or brought the patient to the verge of syncope, the surface of the belly should be *covered* with leeches. From twenty to forty may be applied at once; and sometimes this will make any further loss of blood unnecessary. But in severe cases, you may expect to find that repetitions of at least the local bleeding will be requisite.

After the leeches have fallen off, a light poultice may be laid over the abdomen: or it may be assiduously fomented with flannels wrung out of hot water. These means will encourage the bleeding from the leech-bites; and are generally found to afford great comfort to the feelings of the patient. *Cold* applications have been recommended by some practitioners of high authority. Dr. Sutton injected cold

cnemata, and applied cloths, made wet with cold evaporating lotions, to the abdomen, with good effect; and Dr. Abercrombie has since reported favourably of the same kind of treatment. However, I should think this a more precarious plan than the opposite: and I have always observed so much relief to be given by warm epithems that I have never had the inclination, nor the courage, to employ cold.

It is extremely desirable, in these cases, to obtain as speedily as possible the specific influence of mercury upon the system; by calomel and opium, or by inunction. It cannot be necessary that I should again go over in detail the means of following out this indication; but it is an indication which we must diligently pursue.

The treatment of *puerperal* peritonitis is much more uncertain and difficult; for this reason — that it springs out of an antecedent morbid condition more deeply seated, more generally diffused, and less accessible to remedies than itself. Whenever inflammation arises here and there in the body in consequence of a vitiated state of the blood, we have not only the inflammation itself to deal with, but its physical cause also, which may still be in uncontrolled operation.

Dr. Ferguson justly remarks that “inflammation being made up of vascular and of nervous action, of the afflux of blood to a part, and of pain, it is not irrational to act on both the elements of the malady at the same time, or in periods shortly consecutive of each other.” “The abdominal pain that occurs in puerperal fever, is accompanied by two very different states of constitution; one in which little or no depletion is borne, another in which relief is obtained only by very large evacuations of blood.” Between these two there is very conceivable gradation. “In no malady are a cautious boldness, and a sagacious adaptation of remedy to constitutional power, more imperatively demanded.”

“If large bleeding be determined on, it must, to be beneficial, be resorted to within the first twenty-four hours from the attack. In the second stage of the disease it often produces, rapidly, a fatal result.”

In ambiguous cases he gives ten grains of Dover’s powder, and covers the whole of the abdomen with a large linseed-meal poultice, sufficiently thick to retain warmth for four hours. At the end of that time, if the symptoms are alleviated, “ten grains more of the Dover’s powder, and a fresh poultice, should be prescribed. If within four hours from this second medication, the practitioner is not satisfied that the malady is yielding, he must at once resort to depletion.”

Of all the means we possess of arresting this malady, bleeding, general or topical, is, in Dr. Ferguson’s experience, by far the most extensively applicable. “But,” he says, “while I admit this, I am equally certain that *large* bleeding has not been borne in this complaint, generally speaking, during the last twelve years.”

Another most important truth enunciated by our Professor is, that “epidemic puerperal fever has, invariably, the character common to the ordinary fevers raging with it: if the latter require depletion, the presumption is that the former will also.”

Undoubtedly the very same species of febrile disease is variously affected by a given remedy in different places; and during different periods in the same place. There is such a thing as an epidemic state of the human constitution, gradually produced by a gradual fluctuation in the influences whereby communities of men are surrounded and impressed. The fevers that were cured in London twenty or five-and-twenty years ago by copious blood-letting, would now be rendered by that measure, carried to a like extent, irretrievably mortal. There is scarcely a more important object of study to the practical physician than this different capacity, exhibited by the average of constitutions at different times and seasons, of bearing active depletion. “*Nihil mihi prius est,*” says the wary Sydenham, “*quam quando novæ febres grassari incipient, cunctari paulisper, et ad magna præsertim remedia non nisi suspensio pede, ac tardius procedere; diligenter interim illarum ingenium atque morem observare, quibus itidem præsidiorum generibus ægri juventur vel lædantur, ut quam primum his repudiatis, illis utamur.*” The exciting cause of the fever remains the same; the system upon which it operates undergoes from time to time great changes: which are brought to light partly by the altered phenomena of the disease, partly and chiefly by the effects of remedial measures.

Unless you bear these differences in mind, you will be perplexed and disheartened by the discrepant accounts given by competent and faithful observers, respecting the success of different or even opposite plans of treatment, in the same complaint.

Most writers whose works I am acquainted with, recommend *purgatives* as highly serviceable in peritonitis. I do not think the good which they are calculated to do as antiphlogistic remedies can at all be put in competition with the harm that I am persuaded they may produce by increasing the peristaltic action of the intestines, and so causing additional friction and tension of the inflamed membrane. I believe that in all cases of well-marked and pure peritonitis, when the inflammation is limited to the serous membrane, it is far better and safer to restrain than to solicit the internal movements of the alimentary tube. In a pamphlet published several years ago by Mr. Bates, of Sudbury, some striking instances are recorded of recovery from severe peritonitis under large and frequent doses of opium, and a rigid adherence to the horizontal posture, until all pain had subsided. The patients were not allowed to raise themselves, on any account, into a sitting position: and the opium was administered sometimes by the mouth, sometimes by the rectum. These cases, related in an unpretending manner by a practical observer, made a strong impression on my mind when I read them. To simple inflammation of the peritoneum, to those perilous forms of peritonitis which occur in women after delivery, and to those still more terrible cases that follow perforation of the serous membrane, this principle of keeping the intestines at rest, is alike applicable. I stated a little while ago, that the last-mentioned cases are all but hopeless. The *all but* I inserted on the strength of some most interesting facts published by Dr. Wm. Stokes, in the second number of the *Dublin Journal of Medical and Chemical Science*. He truly remarks, that in most of these accidents the powers of life sink so rapidly that bleeding, either local or general, cannot be attempted. Neither can we employ mercury internally, for fear of exciting the peristaltic action of the bowels, which action would tend to tear asunder recent adhesions, to keep the communication between the mucous and serous surfaces open, and to cause a fresh ingress of fecal or other extraneous matter into the sac. Yet in a few instances we find that the patients live for several days, and that a process of organization commences in the effused lymph. It seems that some years before Dr. Stokes wrote this paper, he had witnessed the admirable effects of opium in low forms of peritonitis, as administered by Dr. Graves; who thus saved, without abstracting a drop of blood, two individuals in whom that disease followed paracentesis. I cannot refrain from quoting to you the particulars of one instance, in which the efficacy of the opiate treatment was conspicuous. The well-known symptoms of perforation of the intestines had existed for two days; the patient was apparently sinking, "his countenance was collapsed, anxious, and expressive of dreadful suffering; the extremities were cold, and the pulse hardly perceptible. The exhibition of sixty drops in the twenty-four hours, of the preparation called the *black drop*, was followed by the most signal improvement. The pulse regained fulness and softness, the extremities became warm, and the countenance had lost the Hippocratic expression. The patient could bear pressure on the abdomen, which the day before was exquisitely painful. The same treatment was continued for twenty-four hours longer; and by the end of that time every symptom of abdominal inflammation had completely subsided. The belly felt natural, there was no tenderness, the pulse was good, and the patient declared himself well." At this period of the case, Dr. Stokes omitted the opium, and gave the mildest possible saline laxative, as there had been no stool for forty-eight hours. Four evacuations took place, followed by the immediate return of the symptoms of peritonitis, under which the patient rapidly sank.

"The intestines were everywhere agglutinated together, and adherent to the parietal peritoneum, except in the left iliac fossa, where a quantity of yellow puriform matter was collected. On detaching the caput coli from the peritoneum lining the right iliac fossa, a small perforation of the gut was discovered, by the escape of the contents of the intestines in a jet," &c. &c.

This example puts in a very strong light the *good* effects of *opium*; the *dangerous* effects of *purgatives*; and the *mode* in which recovery from these frightful accidents may sometimes be brought about.

Dr. Stokes gives another instance in which the patient *did* recover; after taking 105 grains of opium, besides what was administered in injections: and he alludes to a third case, in which the employment of opium was successful, when peritonitis had supervened upon the bursting of an hepatic abscess into the cavity of the abdomen.

Now I would earnestly recommend you to consider the expediency of applying the

same principle of treatment, as an auxiliary, when the peritonitis does *not* grow out of previous organic disease: in all cases, in short, of *mere peritonitis*. The opium is not to supersede the bleeding, or the mercury; it is not incompatible with either of those remedies; and it may, I believe, be most advantageously adopted in conjunction with them both.

When the time arrives at which it may seem expedient that the bowels should be emptied, it is better, in the first instance, to employ enemata for that purpose, than to give purgatives by the mouth.

I shall relate one example, which has lately occurred to me, of the successful use of opium in simple, but severe peritonitis. Several of you saw this patient. His case was published in the appendix to Dr. Ferguson's volume.

II. Middlehurst, a tailor, seventeen years old, was admitted into the Middlesex Hospital on the 17th of September: looking very ill, and complaining of pain in the epigastrium, with extreme tenderness over the whole abdomen, which was full and tense. He had been ill several days, had shivered in the outset; and had vomited frequently, up to the period of his admission. His bowels were confined; his tongue was dry and white.

Twelve leeches were placed upon his abdomen, and calomel, in five-grain doses, was given two or three times at intervals of four hours. An enema of warm water was injected, and retained. In the evening sixteen more leeches were applied, and a drachm of mercurial ointment was rubbed into his arm.

I first saw him on the 18th. His countenance was then pinched and anxious, and he lay moaning with pain; his knees being drawn up towards his belly, which was tense, and exquisitely sensible to pressure. He complained of nausea and retching, but had not vomited since his admission. His tongue was thickly coated; his pulse small, sharp, 108 in number. No permanent relief had been obtained from the leeches.

I directed immediate venæsection; but not more than four ounces of blood could be got from the arm. Thirty fresh leeches were therefore put upon the abdomen, and afterwards a warm poultice to receive the blood from their bites. Three grains of calomel, and three of blue pill, were ordered to be given every four hours.

The last leeches mitigated the pain; but it returned in the evening with increased severity, and he vomited the pills. He appeared to be in great agony. In this state the apothecary gave him twelve grains of calomel, and five grains of opium, in one dose. Soon after this he fell asleep; and slept during the greater part of the night. Next morning his countenance had lost, in a great degree, its expression of anxiety; his belly was less tender, but still tense; and his tongue cleaner. No stool.

Capiat Pilulæ Saponis cum Opio gr. v. 8vā. quāq. horā.

On the 20th the bowels were freely open, the dejections dark and watery; the abdomen was less tender. Pulse 114. He continued to take a grain of opium three daily till the 3d of October: the bowels being every day moved; the pulse and tongue gradually improving; and the abdomen being painless even under firm pressure. On the 3d, as the bowels had not acted for the last two days, I discontinued the opium. On the 5th, diarrhœa set in, with some renewed tenderness of the belly; and the pinched and anxious countenance returned. He had then an opiate enema; and resumed the opiate pills as before. Under this treatment he at length got quite well; and left the hospital on the 30th.

Chronic peritonitis is sometimes merely the sequel of that acute form of inflammation of the peritoneum, which I have just been describing. Plastic lymph is effused, and becomes organized; serous fluid is poured out, and is not absorbed again; the products of the original inflammation remain; a low degree of inflammatory action perhaps remains also, or is re-excited by slight causes; the mischief augments; and the patient is slowly conducted to the grave.

There is, however, another, not at all uncommon, and equally formidable source of chronic peritonitis; the presence, I mean, of a multitude of little granules, lying within or immediately beneath the membrane, or occupying, in countless numbers, those folds of the peritoneum which compose the omentum. These granules occur principally, if not exclusively, in serofulous persons. Louis, indeed, who considers them to be *tubercles*, affirms that they are never met with in the peritoneum, without

being met with also—and usually in a more advanced state and greater abundance—in the lungs; but this rule is not universally true. I have seen more than one instance of well-marked granular disease of the serous membrane of the abdomen, without a single tubercle in the pulmonary tissues. Still the observation of Louis holds good in a vast majority of cases: and when we have symptoms of chronic peritonitis, which were not preceded by those of acute inflammation of the membrane, and when we perceive at the same time indications of phthisis, or of any other unequivocal form of scrofula, we shall seldom be wrong in connecting the chronic peritonitis with the presence of these miliary granulations. Whether they are truly scrofulous tubercles, or whether, as some suppose, they are *sui generis*, or again, simply minute spherules of coagulable lymph, I do not undertake to determine. I have been in the habit of regarding them as the cause, and not as the consequence, of the inflammation with which they are found associated.

The *symptoms* of chronic inflammation of the peritoneum are more obscure, in general, than those of the acute disease. And when the disorder is primitive, not the relics I mean of more active inflammation, it often begins, and steals on, in a very insidious manner. The patient complains of abdominal pains: sometimes slight, amounting to scarcely more than uneasiness, but abiding; sometimes occasional only. Usually there is a sensation of fulness and tension of the belly, although its bulk may not be sensibly altered. Sometimes there is a sense of pricking felt. Dr. Pemberton remarks, that you may detect a sort of deep-seated tension; that the skin and muscles lie loosely on the peritoneum, which gives to the hand a sensation as of a tight bandage underneath, over which the integuments appear to slide. The uneasiness, or the pain, is augmented by pressure; or perhaps is felt only when pressure is made. Sometimes the functions of the intestinal canal are disturbed: there are loss of appetite; nausea and vomiting; an irregular state of the bowels, and unnatural evacuations from them. Sometimes, on the contrary, the digestive organs perform their office in a tolerably healthy manner. These differences depend apparently upon the circumstance of the inflammation visiting, or sparing, the peritoneal covering of the stomach and bowels; and of the parts concerned in the secretion of bile. Sooner or later, in most cases, the abdomen enlarges; becomes tight, and tympanitic; and fluctuation is felt. All along there is some fever, more or less distinctly marked; with progressive emaciation and debility. The face is pale and sallow, and wears an expression of languor.

Very much the same set of symptoms are apt to result from scrofulous disease and enlargement of the mesenteric glands; and consecutive slow inflammation of the peritoneal membrane.

Accordingly, after death, we often find those glands swelled, and red, and hard; sometimes forming very large tumours: or we discover the whole surface of the membrane to be thickly bestrewed with innumerable small, round, greyish, or white granules: or it is seen to be covered, here and there, or everywhere, with false membranes. The intestines, full of air, are frequently agglutinated into one mass; or they are adherent to each other, or to the other parts of the peritoneum, in places only. The omentum is generally thick, red, and fleshy, as if its component parts had been matted together; and there is more or less fluid, commonly turbid and flaky, in so much of the cavity as happens to be left.

These are very unpromising forms of disease, and it is seldom that we can do more than mitigate the most distressing of the symptoms; or retard, perhaps, the march of the disorder. Leeches to the abdomen, in moderate numbers, and frequently repeated, and followed by soft warm poultices. Blisters, when the pain is not severe, and the tenderness less. Attention to the state of the bowels, which should be regulated by mild laxatives rather than by drastic purges. A nourishing, but unstimulant diet. These are the measures to which we must look for benefit. It has been thought that frictions upon the belly, with ointments containing iodine, have done good: so that it may be well to make trial of such. But do what we may, in nine cases out of ten, our best directed efforts will be disappointed.

When there is much fluid collected in the abdominal cavity in these cases, they take their character from this predominant symptom, and are called cases of *ascites*. But this is only one form of *ascites*—that form which results from chronic inflamma-

tion of the peritoneal membrane. I shall pass, however, by an easy transition, to the other forms of dropsy of the belly.

There is another species of ascites, not very common, which approaches in its character to inflammation, and which is therefore called *active* ascites. I mean that we sometimes see persons, who were previously in good health, become rapidly ascitic, after exposure to cold and wet, and rapidly recover again under the remedies that are used to subdue inflammation. Perhaps it may be said that these *are* cases of inflammation; and it may be so. But they want many of the ordinary symptoms of peritonitis; and if inflammation *be* present, it has no worse effect than the effusion of serum, which, under depletion or mercury, is speedily taken up again. I should rather conceive, however, that these cases are to be included in that category of dropsical effusions which I spoke of formerly, as resulting from the detention in the blood, or from the absorption into the blood, in the first place, of an undue quantity of watery fluid, and its subsequent discharge, by a kind of secretion, either into shut cavities, or through some one of the natural vents of the body. The balance of the circulation between the skin and the internal surfaces appears to be destroyed on these occasions, by the operation of external cold upon the tegumentary membranes.

But by far the greater number of cases of ascites are cases of passive dropsy which arise slowly from a mechanical obstacle to the free return of the venous blood towards the heart.

Ascites occurs, as you know, in general dropsy, with anasarca of the universal areolar tissue; and this general effusion of fluid depends, in almost every case, either upon a peculiar renal disorder, or upon organic disease of the viscera of the thorax; of the lungs, or of the heart, or of both; and, above all, upon such disorder as is attended with dilatation of the right chambers of the heart.

But I exclude this form of ascites, wherein the dropsy of the belly is only a portion of more general disease of the same kind, and limit myself at present to that kind of passive ascites which is unattended with dropsy elsewhere; or which at any rate precedes the occurrence of serous accumulation in other parts.

The symptom which first leads us to suspect ascites, is the progressive enlargement of the abdomen. But the abdomen may grow gradually large and prominent when there is no disease whatever: in pregnancy, for example; or in mere obesity. It is necessary therefore to search for more definite signs of peritoneal dropsy.

In order to make an accurate diagnosis of ascites, we must know what are the morbid conditions with which it is most liable to be confounded. Solid tumours and simple corpulency are readily enough distinguished. But there are certain kinds of *encysted* dropsy of the abdomen, of which the recognition is not so easy and obvious. Of these what is called *ovarian dropsy* is the chief. In some of its symptoms this complaint closely resembles ascites: in some it differs from it widely. So also the treatment of the two disorders is alike in some respects; dissimilar in others. For these reasons, and because I am more solicitous to be practical than to be methodical, I shall consider these two maladies together; turning first to the one, and then to the other, and marking, as I go on, the various points of similitude, and of contrast, which they mutually offer.

Recollect that ascites signifies the accumulation of serous liquid in the bag of the peritoneum; whereas ovarian dropsy consists in the collection of fluid in one or more cells within the ovary; or in a serous cyst connected with the uterine appendages.

One source of distinction between the two is furnished by the condition of the abdomen during their early stages.

In ascites the enlargement is uniform and symmetrical, in reference to the two sides of the body. When the patient lies on her back the flanks bulge outwards, or swag over, from the weight and lateral pressure of the augmenting fluid. This increased *breadth* of the trunk is not observable in the case of an ovarian tumour; nor, I may add, in pregnancy.

When we are able to trace the early history of ovarian dropsy, we find, in most instances, that the abdominal tumour was first perceived on one side; in one or the other of the iliac fossæ, or somewhere between the ribs and the ilium. But when the enlargement of the abdomen is great, the distinction between ascites and encysted dropsy, drawn from the shape of the swelling, fails. The ovarian tumour distends

the abdomen, if not uniformly, yet nearly or quite as much on one side as on the other.

The next thing that we do, when the *visible* bulk and shape of the abdomen have suggested a suspicion of ascites, is to employ the sense of *touch*.

Examination by *pressure* will sometimes suffice to assure us that there is fluid in the peritoneum. If you press suddenly with the tips of your fingers, in a direction perpendicular to the surface, you will often become aware of a sensation which it is difficult to describe in words, yet which is quite decisive, and not to be mistaken; a sensation of the displacement of liquid, and of the impinging of your fingers upon some solid substance below. So that, by this manœuvre, you frequently detect, not merely the presence of the liquid, but an enlarged liver, or spleen, or (it may be) an ovarian or other tumour; even when simple palpation, or handling in the ordinary way, would not enable you to ascertain these enlargements.

Again, *percussion* of the abdomen is fertile of information in these cases. First, by the sense of fluctuation which it causes when liquid is collected within. The left hand being laid flat against one side of the tumid abdomen, if a slight blow be struck with the fingers of the right upon the opposite side, the impulse is conveyed by a wave of the liquid to the open flat hand, which feels a little shock that is perfectly distinctive. The larger the amount of the accumulated liquid, and the thinner and tighter the walls within which it is confined, the more sensible and decided is this fluctuation. Even when the quantity is small, not exceeding a few ounces, a little practice and management will enable you to detect it. Percuss with one finger the most depending part of the cavity, and apply at the same time a finger of the other hand, very near the part struck; and if liquid be there, you will perceive a limited yet distinct fluctuation. In the same way the presence of liquid in a small cyst may sometimes be ascertained. Much more when the cyst is large. And the cyst, in ovarian dropsy, is often very large: and the liquid it contains is often thin and aqueous; and then the fluctuation may be quite as perfect and perceptible as ever it is in ascites.

Hence mere fluctuation is not a discriminating symptom between ascites and ovarian dropsy.

But, secondly, percussion is full of instruction in the *sounds* it elicits. The sense of *hearing* will generally supply what the sense of touch may leave wanting.

In true ascites the relative place of the liquid and of the intestines is determined by the posture of the patient. The bowels, which always contain some gas, float to the upper part of the liquid, and there give out (when the finger, as a pleximeter, is applied to the corresponding surface, and struck) their peculiar resonance. Mediate percussion will thus follow the gravitating fluid, and discover always a dull sound in the lowermost and a hollow sound in the uppermost part of the abdomen.

But it is not so in ovarian dropsy. The cyst, in a diseased and enlarging ovary, rises in front of the intestines, which, being tied down by the mesentery, cannot embrace the tumour so as to reach its anterior aspect, but are in fact pressed back by it towards the spine. Hence, if there be any resonance produced by percussion, it is in one, or the other, or in both of the flanks; and the umbilical region yields a dull sound whatever the position of the patient may be. The same is true of the enlarging womb in pregnancy.

This simple expedient, then, is quite decisive. In ascites, the patient being supine, the epigastric and umbilical regions are tympanitic on percussion; in ovarian dropsy the latter, at least, is dull. To be quite sure it is well to make the patient assume different postures in succession. If the person affected with ascites turn upon her side, the uppermost flank will become resonant; the umbilical region dull: whereas in ovarian dropsy, the sounds under every change of position remain severally where they were. In ascites, with a little care, you may ascertain the exact level at which the contained liquid stands; and measure its rise or fall from day to day.

This mode of diagnosis is scarcely open, under ordinary circumstances, to fallacy, or exception. Yet there are two or three possible conditions in which it may fail; and these it is right that I should briefly mention.

1. The distension, in true ascites, may be so great, that the mesentery shall not be broad enough to allow the buoyant intestines to reach the surface, when the patient is supine. This impediment to the efficacy of the proposed test I have met with in

practice. A woman came under my charge in the hospital with ascites. Fluctuation of the belly was unequivocal. While she lay on her back, the umbilical and epigastric regions were resonant when percussed; the flanks were dull. When she turned upon either side, the other side, previously dull, gave the hollow sound; the umbilical and epigastric regions, previously resonant, gave the dull flat sound. Under the treatment employed, the accumulated liquid was removed, and she left the hospital.

Some time afterwards, as I was going round the wards, I recognised the same woman among the patients recently admitted by my colleague, Dr. Hawkins. The ascites had returned. The abdomen, enormously distended, projected upwards, as she lay on her back, to an excessive height. I found that fluctuation was very distinct, as before: but every part of the belly yielded a dull sound when struck by the fingers. At length this patient died: and it was seen, after death, that there was nothing to prevent the rising of the intestines. They had floated, at the utmost tether of the mesentery, as high as they could, without reaching the surface of the prominent belly.

2. Another occasional source of fallacy I have just now hinted at. The intestines may be tied down, and so prevented from ascending, by their specific lightness, to the upper part of the surrounding liquid. And this may happen, either in consequence of the adhesion of the various coils of the intestines to each other, and to the parts behind them; which is not an uncommon occurrence:—or the intestines, though unadherent, may be swathed, as it were, and bandaged down, by a thickened and diseased omentum. This also I have myself seen. A man died in the hospital, who had manifest ascites. Yet his whole abdomen, though not so much distended as to hinder the intestines, had they been free to rise, from reaching its walls, sounded dull on percussion. Inspection of the body explained this circumstance. When the peritoneum was opened by an incision carried through the fore-part of the abdomen, a quantity of serous liquid gushed out. The floor of the cavity which it had occupied was smooth and level; and was found, on further examination, to be formed by a thick cake of omentum, strapped tightly over the subjacent intestines. Of course, the same diseased condition may occur in the female.

3. On the other hand, I have once known an ovarian cyst to exist, when the umbilical region was tympanitic under percussion. The case furnished just that kind of exception which serves to prove a rule. This also was a hospital patient. Her *history* was the history of ovarian dropsy. Some time previously she had discovered a small tumour in one of the iliac regions. It increased without much disturbance of her general health, until it became very inconvenient from its bulk. She was then tapped in one of the Borough hospitals: and she stated distinctly that it was not a clear watery fluid that was evacuated; but a glutinous, mixed, and grumous matter: such as belongs to ovarian disease. No doubt could be entertained that the enlargement of the abdomen resulted from disease of that kind. Yet the umbilical region, when percussed, always rendered a hollow sound. Upon the death of the patient the mystery was solved. Air hissed forth from the opening made by the scalpel through the abdominal parietes: and the source of it being traced, an ovarian cyst, of considerable magnitude, was found adhering to the peritoneum in front of the belly, and containing no liquid, but some yellowish shreds only; the remains, apparently, of some smaller included cysts. This ovarian bag had been filled with air, and had given occasion to the equivocal sounds.

Another way in which air may sometimes get into an ovarian cyst, and perplex the diagnosis, is through an opening of communication between the cyst and a portion of adherent bowel.

These sources of possible mistake or obscurity very seldom occur; and the physical diagnosis, as I have now pointed it out, is very sure and valuable. So completely physical, indeed, are these tests, that we recognise ascites by them as readily and certainly in the dead, as in the living body.

Other points of distinction may frequently be derived from the history and progress of the two disorders.

The equable enlargement of the abdomen, on both sides, in ascites, and its unequal prominence on one side in the early stages of ovarian disease, I have already mentioned.

Again, it is observable that in true ascites, there are almost always manifest indications of constitutional suffering and disturbance: a sallow complexion; debility; ema-

ciation. The morbid accumulation results (as we shall see) from disease in some organ, of which the functions cannot be impaired without injury to the whole system.

Ovarian dropsy, on the other hand, may last long, and be extreme in degree, while the general health is scarcely affected. The very bulk and weight of the swelling produce, indeed, much inconvenience and discomfort; but, in other respects, the patient often remains in good health. This appears to be owing to the circumstance that the ovary is not directly necessary to the life or well-being of the individual, but is merely subservient, for a limited time, to the purpose of reproduction.

Among the symptoms that are common to ascites and ovarian dropsy in their advanced stages, are all those which are occasioned by weight and pressure: viz. shortness of breath, from the resistance opposed to the descent of the diaphragm; anasarca of the legs and thighs, from pressure upon the inferior cava and its branches; and a peculiarity of carriage and gait, like those of a woman big with child, and depending upon the same cause, the necessity of throwing the head and shoulders backwards, to balance the weight of the distended abdomen in front.

It is necessary to caution you against mistaking a distended bladder for dropsy of the abdomen. An old Frenchman was brought into the Middlesex Hospital, afflicted (so his friends said) with dropsy. He had been treated for that complaint. The abdomen was large, and dull under percussion from the pubes to above the umbilicus. In the hypogastric region I could detect an obscure sense of fluctuation. I noticed a strong smell of urine about this patient. Being interrogated, he said that he had formerly had some "stoppage," but that he now passed plenty of water; that it even ran from him. It was obvious that his bladder was enormously distended, unable to contract upon its contents, and overflowing. With some difficulty a catheter was introduced, and some quarts, I forget the exact quantity, of turbid and stinking urine were drawn off. The patient sank at length, and the bladder was found to be much diseased. I have known several similar mistakes to occur in private practice. You will not think the caution I am now giving you superfluous, when I tell you, on the authority of Sir Everard Home, that no less a surgeon than John Hunter once actually tapped a distended bladder, in the belief that the disorder was ascites.

Encysted dropsy, in the abdomen, is not always *ovarian dropsy*. *Omental dropsy* is described: the omental cavity alone being unfolded, and full of liquid. This I have never seen. Cysts containing a considerable quantity of a clear thin liquid, and connected with the *liver*, are common. Probably these are in all cases (they certainly are in many) the effects of the growth of hydatids. Dropsy of the *fallopian tubes*: dropsy of the *uterus*: large serous cysts in the *kidney*: constitute other forms of abdominal encysted dropsy. Such states must be discovered by their own particular circumstances. None of them are very common.

LECTURE LXVII.

Pathology of Chronic Ascites; of Ovarian Dropsy. Treatment of these two disorders. Internal remedies: Extirpation of the ovarian sac: Paracentesis Abdominis.

IN my last lecture I pointed out the means we possess of distinguishing ascites from ovarian dropsy. Continuing the parallel between these two disorders, I have still to consider their pathology; and to prescribe their treatment.

I mentioned that chronic ascites is sometimes the sequel of acute inflammation of the peritoneum. In such cases, the abdomen is usually uneasy, and tender under pressure; or, at any rate, more than commonly sensitive: and I believe more than commonly *hot* also. Whereas when ascites is passive as well as chronic, you may make the requisite examination without causing any distress to your patient. There is no pain produced by palpation, by percussion, or by pressure. Even when the

dropsy has resulted from bygone inflammation, it does occasionally happen, though rarely, that no other trace of such inflammation is discoverable in the *living* patient. The absorbing function of the membrane having, however, been spoiled, the collected liquid remains. Such a condition, I believe, I have witnessed. The history of sudden and sharp pain, and tenderness of the abdomen, with fever, immediately before the dropsical swelling took place, made it probable that it was the consequence of inflammatory effusion. But the fever had entirely subsided; no tenderness was left; no large veins were visible on the surface of the belly, denoting internal obstruction; and the general health was good. The patient had no other dropsy.

The main exciting cause, however, of true and uncombined ascites, when no inflammation is, or has been, at work, is some impediment to the venous circulation in the abdomen. Whereabouts, and of what kind, is this impediment? That is the question which, in each particular instance, we ask ourselves.

The old doctrine respecting the causes of ascites, vaguely referred the collection of liquid to *obstruction*; and to *organic diseases* of the abdominal viscera; and, above all, to *hepatic* disease. But as we are now better instructed, and know that organic diseases produce the dropsy, ultimately, by retarding the flow of blood through the system of the vena portæ, we see that the truth was only half perceived by the ancient pathologists. We can now understand why some organic diseases of the abdomen lead to dropsy of the peritoneum, and others (even of the same viscus) do not. And we have no difficulty in comprehending why, of all the abdominal viscera, the *liver* is the one of which the diseases are the most frequently connected with ascites; that gland being traversed by the converging branches of the venous trunk, through which passes by far the greatest part of the serosity absorbed from the surface of the vast membrane that inwraps most of the abdominal organs, and lines the cavity containing them. It is plain that an accumulation of serum in the peritoneal sac may arise from a mechanical obstruction in the trunk of the vena portæ, or in some of the principal branches that unite to form that vein; or from certain diseases of the liver itself. But we know that disease of the liver is of very common occurrence, and oftentimes very obvious, while there is no ascites. And a further question arises—With what kind of disease of the liver is hepatic ascites most apt to be associated?

In truth, there is one special form of liver-disease which, though not the sole, is the grand cause, of passive and simple ascites. It has long been noticed that mere enlargement is not the most common condition of the liver met with in hepatic dropsy; but rather the small, hard, contracted viscus. Mere increase in the size of the organ may interfere but little with the portal circulation; whereas a shrinking and diminution of its bulk must needs do so. In point of fact, that particular state of the liver which the French have termed *cirrhose*, and which is familiar to morbid anatomists in this country as the *lobnailed* liver, is the great source of passive ascites.

The true character of this remarkable condition of the liver is of modern discovery. The credit of correcting the erroneous opinions which had been entertained respecting it is due, I believe, to Mr. Kiernan. The change undergone by the organ has also been clearly described by Sir R. Carswell; whose delineations of its physical appearance are now before you. The change results from chronic inflammation, and chronic thickening (miscalled hypertrophy), of Glisson's capsule. Since Mr. Kiernan's admirable exposition of the minute anatomy of the liver has been given to the world, few can be ignorant that the areolar tissue, termed the capsule of Glisson, accompanies the portal vein, the hepatic artery, and the biliary ducts; and forms a sheath around these vessels in their course through the liver; while the hepatic vein and its branches are lodged in the proper substance of the gland without any such investing membrane. It follows that a general thickening of this tissue must produce a general pressure upon the portal veins, large and small, and hinder the return of the venous blood from the intestines. Hence, as in analogous cases, congestion of the capillaries, arrested absorption, mechanical transudation of serous liquid. The pressure affects also the nutrient vessel, the artery of the liver; so that, in most instances, there is atrophy and shrinking of the organ; and occasionally, though rarely, jaundice also ensues, from pressure upon the biliary vessels. By degrees, the areolar tissue itself begins to shrink; and the spaces in which it ramifies on the surface of the liver are pulled inwards; the lobules appear to be prominent; and the sur-

face becomes irregular and knobby, and studded with little roundish eminences like the heads of nails. The constricted lobules are likewise very conspicuous in the cut surface of the liver: appearing like a congeries of peas, of a pale yellowish colour.

In the living body the presence of this hepatic disease is, for the most part, a matter of inference only. It is rendered probable by its ascertained frequency in connexion with ascites, and by the absence of any other obvious cause for the dropsy. But sometimes the irregular surface can be felt through the walls of the abdomen.

The nature of this morbid change affords a reason for the intractable and unpromising character of ascites in general. The obstructed blood seeks indeed new channels; but the compensation they furnish is rarely sufficient. The portal blood is diverted towards the vena cava and its tributaries. The superficial veins become obvious, numerous, large; and wander with many inosculations over the surface of the belly. Large veins, significant of the same compensating effort, have been met with also in the adhesions which previous inflammation had left between the liver and the diaphragm.

Among the causes to which the thickening of the capsule of Glisson may be ascribed, habitual intemperance holds the chief place. The diagnosis will be assisted therefore by our knowing that the patient has been a spirit drinker. The liver in question is the true gin-drinker's liver. It must arise from other causes also, for we sometimes meet with it in the bodies of children, and of adults who had always lived temperately: but in ninety-nine cases out of a hundred, it is traceable to the repeated operation of the poison of alcohol. In dogs that had been destroyed by this poison, Dr. Percy recovered alcohol from the blood, the brain, and other parts, but most of all from the liver; and Dr. Budd, who has exhausted the subject of diseases of that organ, concludes that the alcohol, absorbed into the veins, is conveyed at once to the liver, and exercises a direct action upon its tissues.

But this condition of Glisson's capsule, though it is the principal, and by far the most frequent, is not the only cause of obstruction to the current of the blood in the portal vessels, and of consequent ascites. In those specific forms of liver disease in which separate tumours are scattered through its substance, one of these tumours may be so placed as to press upon the trunk of the vein. So, obviously, may abdominal tumours of any kind; enlarged mesenteric glands; cancer of the pylorus; cancer of the head of the pancreas; and the like.

Ascites is found to be not unfrequently associated with disease and enlargement of the *spleen* also; but in most instances of this kind, the enlargement of the spleen and the peritoneal dropsy are not connected as cause and effect; but are both consequences of portal obstruction.

When, after death preceded by ascites, the cavity of the abdomen is laid open, its contents present a bleached and sodden appearance. It has been made a question whether this be the result of the long-continued immersion of the living tissues in the accumulated water; or of their short maceration after death. The question has no practical importance.

FIG. 101.

Incipient cyst-formation. The ovary is represented of the normal size.

Dropsy of the ovary in its ordinary form, consists (I believe) in disease and enlargement of one, or more, of the Graafian vesicles; or of the ova which they inclose.

The actual condition of the dropsical ovary is subject to much variety. Sometimes there is but one cyst; and this may be no bigger than a pea; or it may be large enough to contain many gallons. Its walls may be as thin and flexible as those of the healthy urinary bladder; or they may be firm, and half an inch or more in thickness. It may spring from a small pedicle, and lie free and otherwise unattached in

the cavity of the peritoneum; or it may adhere, partially or at all points, to the contiguous surfaces; or it may be tied and tethered by bands of coagulable lymph. Its inner surface may be smooth and even, or knobby and irregular. Lastly, the fluid contained in the cyst may be thin, or consistent; limpid, or glutinous; opaque, or transparent; and of various tints; so that, in different cases, it may be colourless, green, purple, red; and more or less resemble in appearance, pure water, white of egg, jelly, glue, birdlime, or treacle. Most commonly, however, when the cyst is single, its contents are thin and aqueous.

Again, the dropsical ovary may be multilocular, composed of many cysts, which are

FIG. 102.

Ovarian cyst. From a preparation in Dr. Gross' cabinet.

usually distinct, but which sometimes communicate together; and these cysts, in the same ovary, while they vary much in size, may differ also from each other in any or in all the particulars just enumerated as being incidental to a solitary cyst.

Commonly one of the cysts is much more capacious than the rest; and some part of its inner surface is frequently embossed, as it were, by the projecting outline of a group of small nodules, which seem to lie within the parietes of the larger cyst, but which, in truth, are cysts of similar origin with it, but of more stunted growth.

The external surface also of the multilocular ovary is generally lobulated; and its inequalities may often be discovered by a careful examination of the abdomen in the living subject.

Sometimes the tumour is solid throughout; in which case the term dropsy is altogether misapplied.

These differences are not without occasional importance, in reference to some points in the treatment of the disease.

FIG. 103.

A multilocular ovarian cyst, removed from a female, æt. 29, during life, by Mr. J. B. Brown. Septa form larger compartments, in which there is a secondary and tertiary growth of cysts. The tumour weighed 11 lbs. 3 oz.

The *progress* of ovarian dropsy is no less wanting in uniformity. Sometimes it is very rapid; sometimes it is very slow. It may destroy life in a few months; it may continue, a mere burden, with scarcely any fatal tendency, for many years. Not unfrequently, after a period of active increase in the tumour, the morbid process, without any obvious cause, suddenly stops: and the pause may be final; or, after an uncertain interval, the disease may resume its former activity.

Under all circumstances the malady is a serious one; for its possible grievances are many; and its issue is precarious and unpromising. Although, in some cases, the general health for a long time is but slightly, or not at all impaired, in others the disease runs a short

course; the tumour increasing rapidly and proving ultimately fatal by its bulk and pressure; or embittering and abridging the unhappy patient's existence by some accident of growth or position. Even when of no vast magnitude, it may be so

situated as to impede or prevent the expulsion of the fæces from the bowel, of the urine from the bladder, or of the fœtus from the gravid uterus.

The single cysts, having thin parietes, and containing a serous liquid, are not always produced by disease and distension of a Graafian vesicle; for they sometimes have no connexion with the ovary, but spring from some other part of the uterine appendages.

Neither, perhaps, can it be *demonstrated* that the complaint originated within the Graafian vesicles, when it exists in its more complicated form; when the cysts are many, and their contents various. But the shape of the cysts, which is more or less spherical, their number, their isolation in most cases, and the diversity in the matters by which they are filled, render this view of their origin at least a probable one.

This form of the disorder has been considered as belonging to the category of *malignant* diseases; but, in my judgment, without sufficient reason. It is true that the tumour does sometimes involve one or more of those morbid conditions, which have been denominated scirrhus, fungus hæmatodes, cerebriform disease, or melanosis, and which all, or nearly all, appear to be varying results of the same morbid process, and to be referable to the genus *carcinoma*; but whenever this is observed to be the case, other structures also are found to be infested with analogous changes. The so-called malignant disease occupies the ovary in common with other parts; and this is one of its most constant characters, namely, that proceeding from some vice in the constitution, or disseminated from some local germ, it pervades different organs of the body at the same time, or in succession; whereas in by far the majority of instances of ovarian dropsy, these peculiar products are met with neither in the diseased gland, nor in any other place. It has already been remarked that many women, labouring under ovarian dropsy, enjoy nevertheless in all other respects very good health, even for many years. The victims of malignant disease are not so fortunate. *They* either are soon cut off, or, if they linger, they seldom fail to exhibit, in their complexion and general condition, notable indications of the mischief which is in progress, and gradually undermining the powers of life.

If it be admitted, as a reasonable conjecture, that the Graafian vesicles, or the ova they contain, are the seat of the primary changes, we may push our speculations a little further. These ova are destined, under the peculiar stimulus of impregnation, to build up the fabric of the body in all its parts and qualities. And we may suppose that, in consequence of some unnatural and morbid stimulus, perverted and erring action may be set up, and strange products result. It is not uncommon to find fat, hair, cholesterine, teeth, and other bones, in the diseased ovaria, even of virgins.

This view of the matter is strengthened by the fact, that dropsy of the *ovary*, of the ordinary kind, has not been known to *commence* before the age of puberty; nor often after the capability of child-bearing had ceased; but only, or chiefly, during that period in which the organ, if healthy, is susceptible of its proper and temporary function. Virgins, and barren and fruitful wives, are alike subject to the disease; but in what relative proportions, statistical inquiry has not yet (so far as I know) determined. Where it accompanies, it may also account for, sterility.

The catamenia during the progress of the malady sometimes appear with more or less of punctuality and quantity; sometimes are entirely suspended. This function is so often interrupted under other circumstances, that its derangements shed but little light upon cases that are otherwise obscure. When the discharge continues to recur, we may presume that one, at least, of the ovaries is in a tolerably healthy state: when both are sensibly diseased, the catamenia may be expected to be wanting.

The *treatment* of these two forms of abdominal dropsy must, up to a certain point, at which the operation of tapping becomes expedient, be considered separately. Of both it may be said, that their cure is seldom accomplished; yet, for reasons already assigned, ascites has, upon the whole, a more certain progress towards the destruction of life than ovarian disease: while, perhaps, it is oftener cured.

In passive ascites, when the distension of the peritoneum has crept on without pain, fever, or other marks of inflammatory action, our first and best hope of evacuating the collected fluid will rest upon diuretics. Hepatic ascites and renal disease may be sometimes found in conjunction, but according to my experience, they seldom are so: and except that both may probably owe their occasional origin to habits of

intemperance, there appears no reason why they should be. Diuretics may be administered, therefore, without scruple. The hydragogue purgatives are to be employed, also, when diuretics fail to act, or to reduce the swelling; and when the disease is not already complicated with diarrhoea. And inferring with more or less certainty the existence of hepatic disease—sometimes from palpation of the enlarged or altered liver, sometimes from the coincidence of jaundice, and from the history and habits of the patient, but most of all from the result of accumulated experience respecting the morbid anatomy of such cases—we give the patient the chance of the remedial influence of mercury. The disorder being chronic, the introduction of that drug should be gradual. The iodide of potassium is held by some physicians to be especially serviceable in hepatic ascites. Compounds of mercury and iodine may be applied, by inunction, to the surface of the abdomen, and to the right hypochondrium in particular. In Germany, the muriate of ammonia is in much repute as a therapeutic agent. This diuretic salt, though seldom administered internally in this country, is believed by some practical men who have employed it, to exercise the same beneficial influence upon the functions of the liver, as is commonly attributed to preparations of mercury; while it is less productive of distress or inconvenience. My own experience upon this point is too limited to justify me in expressing any confident opinion about it; but in some recent instances I certainly have noticed a remarkable improvement in the character of the biliary excretion, after the daily exhibition of sal-ammoniac combined with the extract of taraxacum.

You will generally be obliged to try, in their turn, all the diuretics within your reach, and frequently to no purpose. Our efforts to remove by medicine the accumulated liquid, or to cure the morbid condition on which the accumulation depends, are too often made in vain. The distension of the peritoneum continues to augment; the distress therefrom arising becomes urgent and extreme; and at length, to afford temporary ease to the patient, and in the faint hope also of giving him permanent relief, we resort to the mechanical expedient of *paracentesis*.

When we have the opportunity of treating *ovarian dropsy* from its commencement, we sometimes find that the enlarging ovary is painful, or tender. This is an indication for *antiphlogistic* measures. But from such remedies, or from any remedies, little more than temporary relief is to be expected. My position as physician to a hospital, has brought under my notice many cases of ovarian swelling, at a very early period of its development; when all that could be detected by careful examination of the abdomen was a small tumour, not larger, perhaps, than an egg, and occupying the situation of the ovary; to which tumour the attention of the patient had been drawn by some pain or uneasy feeling in that part. I have treated such cases assiduously, with the remedies of chronic inflammation, frequent topical bleedings, and the use of mercury till the gums were affected: with the remedies of ordinary dropsy, diuretics and drastic purgatives: and with remedies accounted specific; the liquor potassæ, the various preparations of iodine: and I must honestly confess to you that I am unable to reckon one single instance of success. Yet these are the measures that we are bound to try. They have succeeded—as we are assured by competent and credible witnesses: they may therefore succeed again. The amount of my own experience, however, tends to the persuasion that medicine has, in general, very small influence over the progress of this disorder. The cases that do well, do well we scarcely know how or why; the cases that prove fatal run their course in spite of us.

Sometimes, as has been stated, these ovarian tumours reach a certain magnitude, and then (wherefore we cannot tell,) enlarge no more; but remain, a mere inconvenience and deformity, for many years. Occasionally, either spontaneously, or in consequence of some accidental violence, they burst into the cavity of the peritoneum, whence the effused fluid may be absorbed; but more commonly it causes fatal inflammation. Or the bursting tumour may empty itself harmlessly (adhesion having previously taken place) through some channel of communication with the bowels, with the vagina, or with the bladder; or externally through the parietes of the abdomen.

Tumours, supposed to be ovarian, do sometimes disappear entirely. It may, however, be doubted whether all, or even many, of the enlargements which have had this fortunate issue, were really connected with the ovary. One source of mistake I have myself more than once encountered, and I believe it to be not uncommon. A

brief statement of the circumstances under which I first observed the fallacious symptom, will show you at once what I mean. Some years ago I was sent for by a lady, who for many days had been labouring under an ordinary attack of continued fever. While examining the abdomen by pressure, I discovered, on the right side, between the ilium and the umbilicus, a round, hard, painless tumour, as big as a swan's egg. The patient was aware of it; and thought it had existed for some time. At the next visit it was gone. In the interim, very abundant discharges from the bowels had followed the administration of purgative medicine. The tumour had obviously been formed by the accumulation of fecal matters in the cæcum.

Similar collections take place, less frequently, on the left side, just above the sigmoid flexure.

The parts concerned in this disorder are not essential to life, or to the enjoyment of health. On some of the lower animals, the operation of spaying is as customary in the one sex, and is performed with as little risk, as that of castration in the other. The ovaries have in several instances been extracted from the living human body without any ill consequences. These facts, and the intractable character of the disease, have naturally suggested the expediency of extirpating the tumour in cases of ovarian dropsy.

But although the ovary, when healthy, or when not greatly enlarged, may be removed without much difficulty or hazard, the operation becomes always perilous, and often impracticable, when the altered gland has attained any considerable magnitude. Yet these are the very cases for which the remedy is needed. A large ovarian tumour is usually multilocular, with firm parietes, and thick internal septa; and is therefore incapable of collapsing much when punctured. To extirpate such a tumour, the abdomen must be (as it frequently has been) laid open from the sternum to the pubes. Most commonly, also, a large ovarian swelling is adherent to the contiguous parts; a circumstance which either makes the proposed removal of the tumour impossible, or, if the connexions admit of being broken down, augments in a fearful manner the jeopardy of the patient. It is not surprising, therefore, that the results of experience have been so discouraging as well nigh, in most minds, to prohibit such attempts in future. The operation has, indeed, in many authentic cases, been quite successful. In other instances, the surgeon, after exposing the adherent mass, has been fain to replace the effused bowels, and to sew up the abdomen, as speedily as he could; and the patient having suffered all this in vain, has sometimes been fortunate enough to escape with life; but not always. In others, the adhering tumour has been separated, and the object achieved; and the woman has lived thereafter for some hours. Three times, at least (one of the cases is recorded by Mr. Lizars, another by Mr. King, the third fell under the cognizance of Dr. Richard Bright), the abdominal muscles and the peritoneum have been slit open, for the purpose of extracting a diseased ovary, when no disease existed.

But of late, a modification of the process of excision — whereby it is adapted to certain forms or conditions of the disease — has been proposed and practised; and holds out somewhat more of promise.

It consists in making, not a long, but a small incision through the walls of the abdomen, and through the peritoneum, so as to bring the surface of the diseased ovary into view. The cyst is then secured, by means of a tenaculum, or of a ligature, from receding inwards, and punctured, and its contents are suffered to escape. When the sac has emptied itself, it is withdrawn through the external orifice by gentle traction, until its stalk or place of attachment to the broad ligament, comes near the wound. A thread is tied round this stalk, the cyst is cut off, the uterine appendages are put back into the cavity of the abdomen, and the lips of the wound are brought together.

Although this method does not appear to have been actually *performed* till recently, it had been *suggested* as long ago, at least, as the time of Dr. William Hunter, who, in a paper on the disease, has these remarks: — “If it be proposed, indeed, to make such a wound in the belly as will admit only two fingers or so, and then to tap the bag, and draw it out, so as to bring its root or peduncle close to the wound of the belly, that the surgeon may cut it without introducing his hand, surely in a case otherwise so desperate, it might be advisable to do it, could we beforehand know that the circumstances would admit of that treatment.”

In these few words, Dr. William Hunter not only describes the mode of exsision, but alludes to circumstances that may render it inadmissible, as well as to the uncertainty that may arise about the existence of those circumstances. What the circumstances are is sufficiently obvious.

However, this suggestion has been carried into successful practice by Mr. West, Mr. King, and others. To an interesting paper on the subject, published by Mr. Gorham, in the *Lancet*, is appended a summary account of ten cases; by which account it appears, that five of the ten patients were cured by the operation; two recovered from the attempt to extract, which was unsuccessful; two died very soon after the operation, and evidently in consequence of it. The remaining patient, whose case has already been adverted to, recovered also from the incision; but there was no diseased ovary to amputate: so fallacious, sometimes, is the diagnosis. The tumour which she had presented to the notice of the surgeon was what has been called a *phantom* tumour.

This mode of operating merits careful consideration, and further trial. Its recommendations are—

1. That the first steps—the incision and the puncture—are the same in kind as the first steps in ordinary paracentesis, and not much more severe or dangerous; the only difference being that the incision requires to be somewhat larger in the one case than in the other.

2. That, when successful, it affords a complete and permanent cure, which can hardly be hoped for from any other plan.

The objections to its general use are—

1. That the single sacs, with thin and flexible walls, do not, commonly, reach a very large size. When small, or of moderate dimensions, they produce so little distress or inconvenience, that an operation, which must always be uncertain and tentative, ought not to be recommended.

2. That the multilocular tumours, with solid walls and partitions, can scarcely be so drawn through the opening made into the abdomen.

3. And, above all, that adhesion of the tumour to the neighbouring parts would interfere with and frequently prevent the success of the operation.

In most, however, of the five cases of cure referred to by Mr. Gorham, the sacs thus removed were large. From one of them 12 pints of fluid were let out; from another, 27 pints; from a third, upwards of 20; and from a fourth, 24 pints.

It is difficult to guess beforehand whether the tumour be attached to the parts surrounding it or no. If it be readily moveable by the fingers applied to the surface of the belly, so as to admit of being pushed hither and thither without pain or distress to the patient, it is probably unadherent. In one of the same five cases, the patient being in labour, Mr. West found that the tumour lay between the uterus and the brim of the pelvis. By gentle pressure, *per vaginam*, it was made to recede into the cavity of the abdomen. This afforded a presumption that it was free from adhesion; accordingly the sac was afterwards easily excised. The tumour is attached anteriorly to the peritoneum lining the front of the abdomen more frequently than to any other part. This Mr. Gorham attributes to partial inflammation produced by the puncture in the operation of tapping; hence the presumption that the cyst is loose is, *cæteris paribus*, the stronger, when paracentesis has never been performed.

If this mode of exsision should be thought advisable, it ought to be attempted while the tumour is still of moderate bulk, yet enlarging, before the peritoneum has been much stretched, and while the likelihood of adhesion is the least. When any distinct history of bygone peritonitis can be traced, the existence of adhesions may be confidently reckoned upon.¹

¹ Since this lecture was first printed, an interesting paper by Mr. Phillips upon the question of extirpating ovarian cysts has been published in the 27th volume of the *Medico-Chirurgical Transactions*.

Mr. Phillips exhibits, in a tabular form, “the results of 81 operations, performed for the purpose of extracting ovarian tumours. In 61 cases the tumour was extracted; in 15 cases adhesions, or other circumstances, prevented its removal; in five instances no tumour existed. Of the cases in which the operation was completed, the tumour being extracted, 35 terminated favourably; the patient recovered. In 26 instances the termination was unfavourable; the patient died. Of the five cases in which no tumour was found, all recovered.”

To the simpler operation of tapping, the contrary precept applies. Neither in ascites, nor in ovarian dropsy, should paracentesis be resorted to, until it seems absolutely indispensable. To this rule there are, in my opinion, very few exceptions.

The operation itself, though commonly esteemed a trivial one, is not without its dangers. The instances are not few in which it has been followed by fatal peritonitis, excited either by the mere passage of the lancet or trocar through a previously unhealthy membrane, or (in the case of ovarian dropsy) by the escape of some portion of the contents of the cyst into the cavity of the abdomen. To obviate, or to remedy, this source of danger, it is expedient that the bowels should be thoroughly emptied by some mild purgative the day before the operation, and kept quiet for several days afterwards, by moderate doses of opium. Formerly, the rapid evacuation of a large quantity of liquid from the belly was often attended by terrifying effects; fainting, convulsions, almost instant death. This made the ancient physicians afraid of the operation; and when they could no longer avoid it, they let the accumulated fluid out by little and little, and at short intervals.

The cause of these alarming symptoms is now well understood, and easily averted. They were owing, doubtless, to the sudden removal of the pressure to which the viscera and large blood-vessels had been for some time submitted and accustomed. For this explanation of the fact we are indebted to the sagacity of our celebrated countryman, Dr. Mead, who was the first to suggest that external compression should be substituted, in lieu of the tension taken off by the operation. The complete success of that expedient fully justified his ingenious opinion. We now drain the cavity of its liquid contents without scruple or delay. Round the body of the patient, who sits on the edge of a chair or of the bed, a sheet, or broad roller is thrown, and tightened as the fluid escapes, so as to maintain an equable pressure, which is continued for a while, and at length gradually withdrawn. The risk, however, of exhaustion or syncope, and therefore the necessity for this artificial compression, may in most cases be avoided or diminished by keeping the patient, during the performance of the operation, in the horizontal posture, upon his or her side. We owe this practical improvement, I believe, to Dr. Simpson of Edinburgh.

Other casualties occasionally happen; the trocar has sometimes pierced the intestine. In one instance, which I myself witnessed, clear serum issued for some time through the canula, but at length pure blood; not less than a pint. The patient sank; and no opportunity was given of investigating the cause of the bleeding. In another strange but well-authenticated case, the almost incredible quantity, twenty-six pints, of blood flowed out at the orifice made by the trocar, and afterwards separated into clot and serum. To the wonder of those who saw the incident, this patient recovered from the tapping; and the source of the hæmorrhage is still a matter of conjecture.

And apart from these mischances—which, after all, are not of frequent occurrence—you must bear in mind that paracentesis can seldom be contemplated as a mode of cure, but simply of temporary relief from distress. A few instances have happened where the liquid has been drawn off, and has not again collected: but such cases are very rare. So, also, according to my experience, are those, much talked of by authors, in which the kidneys resume their activity upon the removal of the dropsical fluid. Ordinarily, the liquid re-accumulates, often with more rapidity than before; and again, and again, the pain and the hazard of the operation must be repeated; where-

“Of the 15 cases in which adhesions or other circumstances prevented the extraction of the tumour, 9 recovered, 6 died.”

In two other tables Mr. Phillips collects together:—

I. Cases in which a large incision was made, 55 in all: and among these cases there were 26 deaths, 23 cures, and 6 recoveries which were not cures.

II. Cases in which the incision was small (usually under six inches) amounting in all to 27. Among these there were 7 deaths, 13 cures, and 7 recoveries from the unsuccessful operation.

In the 34th volume of the Transactions of the same society, 1851, Dr. Lee has published an analytical table of 162 cases in which the operation has been attempted or performed in Great Britain. “In 60 the ovarian disease could not be removed; 19 of these proved fatal. Of the remaining 102 cases in which the operation was completed, 42 terminated fatally. The present condition of the 60 patients who recovered is very imperfectly known.”

Dr. Clay, of Manchester, states, in 1856, that he has performed the operation in 71 cases, and that 49 of his patients had recovered.

fore, in my judgment, paracentesis in abdominal dropsy ought seldom to be performed, unless the quantity of liquid is so great as to occasion painful distension; or causes great distress of breathing by its upward pressure against the diaphragm; or gives rise to some positive suffering or urgent inconvenience, which the evacuation of the water may be expected to remedy.

Acupuncture of the dropsical belly has of late been recommended; the passage of a grooved *needle*, instead of a *trocar*, through the abdominal parietes. I believe this to be sometimes an eligible and a useful piece of practice. By ascertaining the character of the inclosed liquid, it may settle the diagnosis of a case otherwise ambiguous; but it may do much more. Dr. Robert Lee informs me that he has done this minor operation many times; never with any bad result, generally with relief and benefit to the patient. In one case, ten gallons of liquid escaped from the little puncture. In another, where ordinary tapping was thought unsafe, acupuncture was performed, and fluid oozed freely away for two days and two nights. Great comfort was obtained from this process, and the woman's life was probably prolonged for two years by several repetitions of it. In a third instance, four ounces only of liquid followed the puncture, but a larger portion, which was left behind, gradually disappeared.

It is seldom that tapping is many times performed upon the same person, when the complaint is mere passive ascites. The dropsy returns indeed, and again the operation is required; meanwhile, in most cases, the health and strength rapidly deteriorate and the patient sinks.

The same speedy declension and early death too frequently occur in ovarian dropsy also; yet the operation commonly bears to be repeated more often than in ascites, without serious detriment to the general health. Sometimes the liquid re-accumulates in the cyst very quickly; sometimes slowly; in a very few instances not at all. I have had under my own care a patient who had been tapped for this disease thirty-eight or thirty-nine times. Extraordinary examples of a similar kind are on record; one or two I may mention as specimens.

Dr. Mead narrates the case of a lady, who "for the information of posterity, ordered by her will that the following English inscription should be engraved on her monument in Bunhill Fields:—

‘Here lies Dame Mary Page,
Relict of Sir Gregory Page, Bart.
She departed this life, March 4, 1728,
In the 56th year of her age.
In 67 months she was tapped 66 times:
Had taken away 240 gallons of water,
without ever repining at her case,
or ever fearing the operation.’”

Among authenticated instances, the most remarkable that I have met with is detailed in the *Philosophical Transactions* for 1784, by Mr. Martineau, who was at that time surgeon to the Norfolk and Norwich Hospital. An abstract of the case is given in the printed catalogue of the Hunterian Museum, where the cyst is preserved: it belonged to the left ovary of Sarah Kippus, a widow, fifty-five years old. "The complaint began after a miscarriage, at the age of twenty-seven. From the year 1757, to August, 1783, when she died, she had been tapped eighty times, and had, in all, had taken from her 6631 pints of fluid, or upwards of thirteen hogsheads. 108 pints was the largest quantity ever taken away at any one time. But after death, Mr. Martineau could not make the sac contain more than fifty pints."

Upon the whole, it may be stated of this operation, as applied to ovarian dropsy,—

1. That when it is essential to the comfort and continued existence of the patient, it brings sensible relief to her distress, and often materially prolongs her life;

But, 2. That when it is performed under less pressing circumstances, it tends to shorten the patient's days. Dr. Bright is of opinion that the number is small of those who survive the first tapping more than four years. I question whether even that brief limit might not justly be abridged by one-half. A respectable woman having very large ovarian dropsy, entered the Middlesex Hospital, under my care, for the express purpose of being tapped. The tumour incommoded her by its bulk and weight, but in no other way; and she had carried it for thirteen years. I felt that I

should not be justified in sanctioning the operation in such a case. The patient was made to understand that the performance of it would not be altogether free from immediate danger; and that if she went through it safely, the swelling would return, and the same kind of remedy again become equally necessary. She was instructed how to suspend the heavy overhanging abdomen by a sling passing over her shoulders. There appeared no reason why she should not continue in good health for another period of thirteen years.

I am aware of another instance, in which a woman, similarly burdened, but otherwise in comfortable health, has lived, not without enjoying life, between twenty and thirty years. Had she been tapped when the mere enlargement might have seemed to warrant the operation, she would probably have been for twenty years in her grave.

In connexion with the subject of paracentesis for ovarian dropsy, I must here notice two important points of practice, which, since the foregoing observations were delivered, have been advocated, respectively, by Mr. Isaac Brown of this place, and by Mr. Bambridge, of Liverpool.

Mr. Brown's principle of treatment is the same, in the main, with that propounded many years ago by the late Professor Hamilton, of Edinburgh, but differing in detail; the principle, I mean, of systematic *pressure*. He administers mercury till the gums are slightly tender, and keeps them so for some weeks; giving at the same time diuretics and tonics. Meanwhile the tumour is steadily compressed by a tight flannel bandage. When, under this management, the swelling has for some time decreased, or ceased to increase, the cyst is emptied by tapping. After this operation the cyst and body are again subjected to firm and constant pressure by means of accurately-adapted pads and tight bandages: and the medicines are continued for at least six weeks.

I mention this plan, because of the prosperous results which are said to have followed its adoption. Nevertheless I am constrained to express very serious doubts whether, if tried upon a more extensive scale, it will be found generally successful, or expedient, or even endurable.

Of the other procedure I am more inclined to think favourably. It is simply that of keeping open the orifice made by the trocar, without further meddling by instruments or injections—and allowing the fluid secreted by the cyst to escape as fast as it forms. Mr. Bambridge, who has used this method, adduces (in the 38th volume of the *Medical Gazette*) so many examples of its favourable issue, as to challenge the attentive consideration of the profession. In some of these the opening was artificial, and the experiment intended: in others it was the effect of some fortunate accident, or rather the spontaneous work of nature—whose safe and simple guidings are too often neglected. The theoretic objection to this course seems to be the apprehension that destructive inflammation may ensue in the interior of the cyst, and compromise the immediate safety of the patient. But this fear has not, that I am aware of, been practically realized, under sufficient trial. What most commonly happened, in the cases collected by Mr. Bambridge, was that the discharge gradually became puriform, then grew less, and finally ceased; the aperture closing in some instances, and the recovery being complete—while in others a fistulous opening remained, and the cure was, to that extent, imperfect. Even the great evils of a permanent discharge in this way, would probably be less than those which belong to the ordinary practice. The advantages therefore are, that the empty cyst is permitted to contract, until at last (perhaps) its cavity is obliterated; and that the mental suspense and anxiety, as well as the bodily wear and tear, of repeated fillings and repeated tapplings, are avoided. When the orifice is healed immediately, unless the morbid secretion ceases at once, which it scarcely ever does, the cyst, distended afresh, is prevented from undergoing what would appear to be its natural and radical cure: and its contents are stored up, a useless and hurtful burden, only to be at length evacuated as before. Knowing how well the open drain has answered in some forms of empyema, I should augur hopefully of the same principle when applied to the sad and perplexing category of ovarian dropsies.

Neither indeed of these two expedients is at all new. Each has been occasionally employed for centuries past. But the merits of the last of the two have never, I think, been ascertained with sufficient exactness. Without absolutely counselling its

adoption, therefore, I go so far as to propose it to more competent judges for reconsideration. A further question might arise respecting the most eligible spot for the puncture. Many reasons which I need not specify, as well as a certain amount of experience, would seem to indicate the vagina, as affording a convenient place of outlet.

Another piece of practice in such cases is new; that, namely, of injecting the emptied cyst with a solution of iodine. What the object of these injections may be I do not clearly apprehend. A cure, immediate and radical, like that which is attainable by similar injections in cases of hydrocele, can hardly be contemplated. The arrest of all further secretion from the interior of the cyst seems scarcely more probable. That the danger incidental to the tapping must be greatly enhanced by this expedient I cannot but believe, notwithstanding strong assertions to the contrary. It is an expedient, however, which is at present upon its trial. You will be guided in forming your own judgment of it, not by my misgivings, but by the results of that trial.

LECTURE LXVIII.

Acute Gastritis: symptoms; anatomical characters; treatment. Chronic Inflammation of the Stomach; thickening of the Mucous Membrane; Ulceration; symptoms and treatment of the disorder; Softening and perforation by the Gastric Juice. Cancer of the Stomach.

ACUTE inflammation, when it affects the peritoneum, usually spreads with rapidity over the whole surface of the membrane. This is characteristic of inflammation of the serous membranes generally. But it is not so with the other tissues that compose the alimentary canal. Inflammation of the mucous membrane may be, and often is, very limited in extent: and the different portions of the intestinal tube, as they differ in function, so also they differ somewhat in their diseases, and still more in the symptoms by which those diseases are revealed. Not being fettered by any artificial system of arrangement, I shall take the course which promises to be practically most useful, and consider separately the maladies of the several parts of the alimentary canal in the abdomen, extending my remarks occasionally to the whole of the tube, when speaking of disorders that are common to all portions of it.

Let me, then, in the first place, draw your attention to the organic diseases, and the morbid conditions, of the *stomach*.

It is remarkable, all things considered, how seldom the stomach is affected with *acute inflammation*. Scarcely ever do we find either the organ as a whole, or any one of its tissues separately, the subject of *spontaneous* acute inflammation. What is described in books as *gastritis*, means inflammation of the *mucous membrane* of the stomach: and almost all that we know, for certain, of this disease, we derive from observation of the effects of strongly irritant substances upon that membrane. Idiopathic gastritis, in an acute form, I never saw. Acute gastritis, from the contact of corrosive or acrid poisons, I have frequently seen: and a highly interesting affection it then becomes. This is a subject that cannot be thoroughly discussed in this course of lectures: neither may it be altogether omitted.

When an irritant poison has been received into the stomach and excites inflammation there—or when acute inflammation arises from any cause—the symptoms which mark that inflammation are pain, usually of a burning character, in the epigastrium; with frequent vomiting, especially upon the entrance of any thing into the stomach; and often with hiccup, and with tenderness and tension of the upper part of the abdomen. To these local symptoms are added fever of a low type; and a small weak pulse. At first, indeed, the pulse, although small, is generally sharp and hard; but it soon becomes thready and feeble. The muscular power undergoes a corresponding

depression; the patient is pale and faint, with collapsed features, cold extremities, and a damp skin.

In all this we see a strong tendency to death by *asthenia*. It is clear that the subdued state of the circulation is dependent upon the inflammation, for it is often relieved by the remedies of inflammation. In acute gastritis, as well as in peritonitis, you will find that the pulse expands, becomes more distinct and full, under early bleeding: sometimes even while the blood is flowing.

Upon this remarkable sympathy between the heart and the stomach I have had frequent occasion to insist. You are aware that a smart blow upon the epigastrium may put a sudden stop to the movements of the heart, and induce mortal syncope; without leaving any local trace of its operation. On the other hand, a person in a state of extreme exhaustion and faintness, will sometimes revive at once, upon swallowing into the stomach an ounce or two of brandy, and recover his pulse and colour much too speedily, to allow of our ascribing these effects to the absorption of the alcohol into the blood. Dr. Alison suggests that the depression of the circulation may be attributable to the peculiar sickening pain which accompanies inflammation or sudden injury of the stomach. It appears, however, more probable that the remarkable sympathy in question is governed by the nerves of organic life. The great solar plexus of the ganglionic system lies upon the spinal column immediately behind the stomach. The heart is largely supplied with nervous filaments from the same system. Hence we might almost expect that any sudden stimulus applied to this important plexus would excite, and that any sudden depressing influence would subdue, the natural action of the heart. Upon the same principle may be explained the facts that deadly faintness and nausea are apt to result from injury to the testes, which are also abundantly endowed with influence from the nerves of organic life. Be this as it may, it is important for you to know that the mode of dying in these cases is precisely what Bichat describes as *death beginning at the heart*.

The pain that accompanies gastritis is augmented by pressure upon the epigastrium. It is increased also by the full descent of the diaphragm, and the *breathing* is consequently short and constrained. In the most exquisite cases of gastritis, produced by chemical or mechanical irritants applied to the interior of the stomach, the inflammation probably reaches and involves, more or less, the peritoneum. The patients speak of the pain as a pricking and burning sensation; it is attended with great anxiety and restlessness. The sufferer is tormented with extreme thirst, while all that he drinks, even cold water, is almost instantly rejected by vomiting.

Hiccup does not always accompany acute gastritis. It sometimes occurs early; but more generally it comes on late in the disease, when the patient is sunk and much debilitated.

The bowels, in this complaint, are sometimes bound: sometimes, on the contrary—especially when the inflammation has been caused by corrosive poison—dysenteric diarrhœa ensues, with much griping and tenesmus.

Such, then, are the symptoms that indicate the existence of acute gastritis; but you ought to be aware that they occur in varying combinations, and with different degrees of severity; and consequently that the course of the disease is not uniformly the same in all cases. When the symptoms are the most violent, and the progress of the complaint is the most rapid, the peritoneal coat of the stomach is usually, I believe, more or less implicated.

Intense inflammation of the stomach may be expected to be rapid in its progress. It may destroy life within twenty-four, or even twelve hours. When it is fatal, it generally is so within a few days; and death takes place by fainting; with a remission of the pain, sometimes very sudden, and sometimes occurring only just before dissolution. But as idiopathic gastritis is rare, *fatal* idiopathic gastritis is, of course, still more so. Louis states, that during six years' experience at La Charité, in which period he noted the details of 6000 cases of disease, and of 500 dissections, he did not meet with a single instance of fatal idiopathic gastritis. The subject derives almost all its importance, therefore, from its connexion with poisoning; and the many interesting points of inquiry which arise out of that connexion will be brought before you by the Professor of Forensic Medicine. This consideration is a great satisfaction and relief to me; because I find that the limits of my own course will not permit me to go into any detail in this matter.

The morbid appearances to be looked for after death by acute gastritis, are redness of the mucous membrane, softening, sloughing, and even (after the action of strongly corrosive poisons), perforation of all the coats of the stomach.

I wish particularly to caution you against being misled by mere *redness* of the interior of the stomach; or of the inner surface of the alimentary canal in general; or of *any* mucous membrane; and indeed I may add, of *any serous* membrane also. Redness and inflammation have been made, too often, convertible terms. Persons finding the inner surface of the stomach red, have thence too hastily concluded, that suspicions of poisoning which had arisen, were well founded. We are indebted to Dr. Yelloly, in the first instance, and to M. Billard and some other Frenchmen, in the second, for correcting this error—an error which not only was of importance in questions of imputed poisoning, but has run through and vitiated almost the whole of pathology, both lately and heretofore. Mistaking mere redness for evidence of inflammation, Cullen divided gastritis into two species—one of which he called gastritis *erythematica*; and he inferred from the observation of cases in which redness of the membrane had been met with after death, that this peculiar kind of inflammation of the mucous coat of the stomach might take place, without fever, pain, vomiting, or any other symptom indicative of gastritis: whereas it is almost certain that, in the cases to which he refers, there really was no inflammation at all. So also Morgagni, puzzled by intestinal vascularity, was disposed to attribute the absence of pain, in what he believed to have been inflammation of the bowels, to a paralytic affection which blunted the sensibility of the parts; and Haller conceived, from so constantly meeting with this vascularity in *his* inspections of the body, that inflammation of the bowels was almost always present in fevers of all kinds; and was frequent in every other complaint. And the same doctrine has been strenuously inculcated of late years, as I dare say you know, by Broussais, in France, and adopted by a vast host of his disciples. Finding the lining membrane of the stomach and intestines red and vascular in most of the bodies of patients who had died of fever, Broussais concluded that fever depends, in all cases, upon inflammation of the gastro-enteric mucous membrane. You will perceive that this doctrine is likely to exercise a vast influence upon the *practice* of those who entertain it. If inflammation constitute an essential part of any disorder, it follows that the *remedies* of inflammation will be adapted to that disorder; and thus, even so slight a mistake as that may appear to be, against which I am now cautioning you, of regarding every surface which is red as being inflamed also, may lead to very mischievous views in respect of treatment.

The redness that is *independent* of inflammation may be of various kinds; but the principal cause of it is venous congestion. “The appearances of vascular fulness (says Dr. Yelloly) in the villous coat of the stomach, whether florid or dark-coloured, in distinct vessels or in extravasations of different sizes, are not to be regarded as unequivocal marks of disease; inasmuch as they occur in every variety of degree and character, under every circumstance of previous indisposition, and in situations where the most healthy aspect of the organ may be expected.” To the truth of this statement I can bear witness, having at one time of my life carefully examined, with a view to this matter, a great number of stomachs in succession, in the dead-house of a large hospital. “The vascularity (according to Dr. Yelloly) is entirely *venous*, and depends on a power capable of being exercised on the artery itself at the close of life, which carries on the blood to the veins, after the further supply of fresh blood from the heart is stopped. The branched or stellated form of vessels, under which the vascularity usually appears, is capable of being *imitated*, either by injecting the veins with fine injection, or by forcing back with the finger, or the back of a scalpel, the blood from the larger branches of veins into the smaller.” “And this vascularity soon becomes diffused redness, by transudation of the blood through the coats of the containing vessels, just as happens with the bile in the gall-bladder.”

Redness, from mere repletion of the smaller veins, is usually extensive and undefined; except that, being influenced by the force of gravity, it settles into the most depending parts of the organ, which are either its exclusive seat, or at any rate are of a deeper colour than the parts more elevated. It is attended with an empty state of the arteries, and with a full state of the larger veins. Hence the condition of the venous and arterial trunks, and especially of the vena portæ, should, in doubtful cases,

be ascertained before the main blood-vessels are laid open, and drained of their contents.

The redness that belongs to inflammation is generally circumscribed, and of limited extent; it occupies indiscriminately the upper or the lower side of the tube (for these remarks apply alike to the stomach and to the intestines); it is attended with some fulness of the corresponding arterial trunks; and it may or may not be coincident with comparative emptiness of the venous system within the abdomen. Much will depend, in this respect, upon the *mode of dying*, as I have fully explained to you on a former occasion.

You will please to remember then, in all your future investigations into morbid anatomy, that it is generally difficult, and often impossible, to determine, from the aspect of the vessels of a dead part, from its redness, that inflammation had been present in that part during life, unless the unequivocal products or effects of inflammatory action are present also.

A much more certain evidence of inflammation of the mucous membrane of the stomach and intestines, is its *softening*. This can seldom be attributed to anything else, unless it be to decomposition, or to the solvent action of the gastric juice. Neither of these last causes can come into operation until life is extinct. It is well known that the membrane is slow and late in passing into the state of putrefaction after death. To the effect of the gastric juice in softening and dissolving the coats of the stomach, and to certain important questions respecting their perforation, I shall by and by return.

I say that gastritis is most commonly the effect of poisons applied to the mucous surface of the stomach; but I must include under that head certain substances, which, to most people, are not poisonous or injurious at all, and which only become so to some persons under particular circumstances. Thus, large draughts of cold drink, taken when the body is hot, and rapidly parting with its heat, and especially large draughts of cold *sour* liquors, as cider or stale beer, are apt to give rise to acute gastritis. Another occasional cause of gastritis is the ingestion of very large quantities of food at one time, especially during convalescence from any serious disorder. It is an exceedingly curious fact, too, but one which I merely mention without dwelling upon it, that certain poisons introduced into the body through some other channel, will cause inflammation of the mucous membrane of the stomach, with which they have *not* been in contact. Corrosive sublimate, and arsenic, excite inflammation, with ulceration or sloughing of the gastric mucous membrane, even when they are merely rubbed, in a certain quantity, upon the skin; or when they are applied to the surface of a wound, or inserted into the rectum.

The treatment of acute gastritis is simple. The chief nicety respects the employment of blood-letting. Early in the disease, if the pain be severe, you must *try* the effect of venæsection, notwithstanding the smallness and feebleness of the pulse. How much blood you are to abstract cannot be told beforehand. Take away a small teacupful, keeping, meanwhile, your finger on the wrist. If the beat of the artery do not grow weaker, and still more if it become fuller and stronger, go on with the bleeding, and take another cupful, and another, according to the circumstances of the case and to the effects produced. Apply leeches to the epigastrium, and cover the bleeding bites with a soft, light poultice. Keep the patient as strictly as you can in the horizontal posture: in other words, see that the depressing influence of the disease upon the action of the heart is not aided and augmented by the position of the body. If cold water be retained, that is the best medicine which you can give by the mouth; purgatives so administered would be almost sure to be rejected; and if not rejected, they would be likely to increase the existing inflammation of the organ. Enemata are, however, extremely useful: of warm water, if the bowels are not much confined; of purgative materials if they are. After the intestines have been thus cleared — or when they are loose and irritable — opiate injections (thirty or forty drops of laudanum, with three or four ounces of starch or gruel) do much good. They often have a very tranquillizing effect upon the irritable stomach, and check the vomiting. These measures are to be pursued until the inflammation has subsided. If the stomach be capable of retaining any nutriment at all, it must be given in small quantities, at distant intervals, in a liquid form, and of the blandest kind: barley-water, milk diluted with water, arrow-root, smooth gruel, and the like.

When any *corrosive* substance has been swallowed, I scarcely need say that pains should be taken to remove it as speedily as possible from the stomach : or to administer such remedies as are known to be capable of decomposing the poison, or of affording a specific antidote to it. Not that the stomach-pump should be employed in such cases, as too often it is. These, however, are points that must be fully treated of in the lectures on forensic medicine, and therefore I shall dwell upon them no longer here.

Chronic inflammation of the stomach is probably a very common disorder. Except when it results in ulceration, it does not put life in imminent jeopardy : and it is often recovered from. Deranging, however, the functions, and perverting the feelings of the stomach, it gives rise to the manifold and multiform symptoms of *dyspepsia*. But dyspepsia, with its manifold and multiform symptoms may be, and often is, entirely independent of inflammation. You see, then, why the effects of chronic gastritis are various ; and why the symptoms that are supposed to denote its presence are apt to be obscure, uncertain, and equivocal. I intend, before I quit the subject of the stomach, to investigate the principal circumstances that mark its functional disorders, and to describe the means which we sometimes find conducive to their relief. I shall therefore restrict myself at present to a few points which seem to have been fairly ascertained respecting chronic gastritis.

We know that chronic inflammation had been going on in the stomach when, after death, we see that its coats are thickened ; or when we perceive that a portion of one or more of them has been removed by ulceration.

It is not at all uncommon to find the mucous membrane of the stomach, over a larger or smaller space, thick, granular, uneven, and of an unnatural colour. Gray, or slate-coloured, it often is. This slate colour is much dwelt upon by the French writers, as being a sure and unequivocal impress of chronic inflammation. The colour proceeds, I believe, from the operation of the gastric acids upon the blood, which, under habitual congestion or slow inflammation, is detained in the vessels of the altered part. The ulcers that result from chronic inflammatory action are usually small, varying from the size of a split pea to that of a shilling ; sometimes with no surrounding vascularity or thickening at all, but looking exactly as though a piece of the mucous membrane had been struck out by a stamp ; sometimes with rounded and elevated edges only ; and sometimes they occupy *patches* of thickening and induration

FIG. 104.

Stomach presenting a chronic ulcer; at its upper margin the pneumogastric nerve is shown extending into dense fibrous tissue. The pancreas and the left lobe of the liver formed the base of the ulcer: the latter presents fibroid degeneration of its structure.—From *Habershon*.

of the parietes of the stomach. Generally there is but one solitary ulcer. Its most usual situation is the posterior part of the stomach, in or near its smaller curvature,

and nearer the pyloric opening than the cardiac. More rarely it occupies the anterior part. Now and then an ulcer is found on both the back and front surfaces, at exactly opposite spots. Sometimes two, or three, or more ulcers, are met with in the same stomach. It is very seldom, however, that they are numerous

FIG. 105.

FIG. 106.

Stomach exceedingly contracted from chronic ulceration, with villous growth. Simulating cancer:—

Fig. 105.—External view, resembling colon in appearance.

Fig. 106.—Internal surface, showing ulceration near the pylorus, and villous growth near the centre of the stomach.—From *Habershon*.

Ulcerative disease of the stomach may prove fatal in various ways. The ulcer may penetrate as far as the peritoneum, and excite inflammation of that membrane, whereby the stomach becomes adherent to the neighbouring parts. In these cases, prior or subsequently to adhesion, death may at length ensue, from gradual exhaustion and protracted suffering.

If an ulcer happen to lie over the track of a large blood-vessel in the stomach, it may eat its way into that vessel, and give rise to fatal hæmorrhage.

Or the ulcer may perforate the walls of the stomach, without any previous adhesion, and suffer the food, or the secretions of the stomach, to pass into the peritoneal cavity, where intense inflammation is lighted up, and the patient soon perishes.

Or the ulcers may at length *heal*. Of this we are certain, because we often find cicatrices denoting the spots which the ulcers had occupied.

Our stock of knowledge respecting this dangerous disease, ulcer of the stomach, has been much extended, and rendered more exact, by the researches of living physicians. There are three English volumes which, if you read them carefully, will

furnish you with all that has hitherto been learned on this interesting subject : Dr. George Budd's on *Diseases of the Stomach* ; Dr. Thomas Chambers' on *Digestion and its Derangements* ; and Dr. Brinton's comprehensive monograph on *Ulcer of the Stomach*. In amplifying somewhat the sketch which I have just given you, I borrow chiefly from these writers.

FIG. 107.

Perforating ulcer of the stomach ; the mucous membrane is puckered into folds around it.

this. The healing of such ulcers must be hindered by the alternate stretchings and contractions to which they are subject in the sudden and repeated changes of volume of the stomach, now full and distended with food or with gas, now empty and flaccid : it must be hindered by the vermicular movements of the stomach during the work of digestion ; by the contact of food and drink of various kind and quality ; and probably, as Dr. Budd suggests, by the action of the gastric juice upon the soft and recent lymph, which must needs form the material of repair in the healing process.

Of the open ulcers of the stomach a certain proportion only — about one in four — go through ; become perforating ulcers. And if it be admitted that of the whole number of ulcers there are as many healed as open, then the ratio of the perforating ulcer to the whole number becomes one in seven or eight. This accident of the ulcer is more than twice as common in females as in males : and it is a curious fact, which I am not able to explain, that it occurs more often in maid-servants, between the ages of fifteen and twenty-five, than in any other class of persons. As life goes on, after the thirtieth year, the liability to the formation of a gastric ulcer increases, while the risk of its perforating the walls of the stomach decreases. According to Dr. Brinton, perforating ulcers of the pyloric extremity of the stomach are more common in men than in women.

This risk of going through has some relation to the position of the ulcer ; and it is a relation which is quite intelligible. Perforation is much more frequent in the anterior than in the posterior wall of the stomach. The posterior wall is at once the most subject to ulcers, and the least subject to perforation : it is more closely and more constantly applied to the solid abdominal viscera ; its movements over them are fewer and less extensive ; and it therefore more readily contracts adhesions with them, which adhesions prevents its perforation, in both senses of the word prevent. The threatened aperture is more often stopped by an adherent pancreas than by any other viscus ; but adhesion may take place with the liver, with the colon, or with any part that happens to lie in contact with the stomach. When the colon is the attacked part the ulcer may indeed penetrate into that intestine, but I use the word perforation to express the formation of an opening that communicates with the general cavity of the peritoneum. Without any such communication the ulcer may eat its way beyond the stomach, and produce limited abscess in adherent organs or tissues.

Perforation, when it does occur, may result from sloughing or rupture of the peritoneal coat of the stomach, in the sometimes slow, sometimes rapid progress of the deepening ulcer : but it is more often caused, at last, by pressure of some sort, which suddenly breaks the thinned and fragile membrane. The instant of the rupture is marked by definite and terrible symptoms. It has frequently happened just after a hearty meal ; and during the acts of vomiting, and of straining at stool. It has been known to take place in the effort of sneezing ; under the sudden compression of the

waist by a tight belt; from a rough jolt in a dog-cart. These facts suggest a caution to ourselves—how we handle in such cases the epigastric region, or explore the abdomen by pressure.

A certain number of the ulcers (from 4 to 5 per cent. it is calculated), prove fatal by erosion of a large blood-vessel, and consequent hæmorrhage. As the ulcers most commonly occupy the lesser curvature or the posterior wall of the stomach, it follows that the coronary artery which runs along its lesser curvature, and the splenic which crosses its posterior surface, taking its course along the upper border of the pancreas, are the arteries most obnoxious to this erosion. Here is a drawing after Sir R. Carswell, representing an ulcer which laid open the coronary artery of the stomach and caused fatal hæmorrhage: you may observe that it shows also three scars of healed ulcers. The hæmorrhage is usually abundant, and the vomiting of the blood is preceded by faintness, or actual syncope. It is not however always followed by immediate death. Indeed Dr. Budd states that it was fatal *at the time* in one instance only, among “a considerable number of cases of the kind” that had fallen under his own observation. The bleeding is capable of being somehow staunched, and the injury repaired; and the danger, if not permanently averted, yet postponed. An example of death from this cause is detailed in the *Journal Hebdomadaire*, for May, 1830. The patient had vomited considerable quantities of blood for eight days in succession, five years previously to the attack which terminated his life. So that hæmatemesis from a ruptured blood-vessel in the stomach is not absolutely hopeless.

As this accident of the ulcer is, after all, rare, I will briefly relate an instance of it, which occurred in the year 1831, at St. Bartholomew's Hospital. Dr. Latham, who had charge of the case, was good enough, some time ago, to give me the following history of it. The subject of the disorder was a man thirty-eight years old. He was admitted on the 19th January. His countenance was dusky, but exsanguine; his pulse 100, and weak; his tongue pale, and slightly furred. He made no complaint of pain anywhere.

He had been ailing for two years; had suffered much pain across the epigastric region; and had frequently vomited his meals. Two days before, he had been suddenly attacked with faintness and giddiness, and then vomited about two quarts of blood. He was a habitual spirit-drinker.

In the afternoon of the day on which he entered the hospital, he was again seized with giddiness; and fell into a state of syncope, in which he remained for several minutes. Upon recovering, he vomited a large quantity of blood, not less than three pints. The next morning, early, he brought up a like quantity, under similar circumstances; and he passed three evacuations from the bowels, all of them *black*. He was gradually sinking during the whole of that day, the 20th. Towards the evening, he vomited about half a pint more blood. He died quietly the next morning.

When the abdomen was laid open, the stomach was seen to be distended. The intestines had, in several places, a black appearance; from the colour of their contents. The stomach contained about two pints of coagula, and of a dirty red liquid. At the upper part of its lesser arch was a small excavated ulcer, with hardened edges. In the centre of this ulcer there were visible the orifices of three or four arteries, filled with minute clots of blood.

Blood to a less amount, and by a slower drain, and less arterial in character, darker and more tar-like, may be poured out from many ruptured capillary vessels, in the stomach itself, or in the adherent and eroded pancreas, liver, or spleen.

The symptoms that indicate the existence of ulcer of the stomach are, in kind, the symptoms that accompany chronic gastritis; pain or uneasiness in the epigastrium increased by pressure, increased also on the introduction of food, or perhaps felt only while digestion is in progress; flatulence and eructation; vomiting of mucus, and of the meals; loss of sleep; languor and debility.

By closely observing the course and succession of symptoms of this sort we may often arrive at a tolerably sure diagnosis of the presence of an ulcer.

Some of the most fearful cases of perforation of the stomach, those I mean which are apt to occur in young unmarried women, run apparently a brief course, and are attended with few or but slightly marked symptoms. These patients are, however, mostly anæmic; and when questioned, generally confess to previous dyspeptic feelings. It has been fancied that some derangement of the uterine functions may be

influential in causing this mysterious and terrible form of ulceration : but it has happened prior to the period of puberty, and when the menstrual flux has been complete and regular, as well as when it has been scanty and suspended. The ulcer has always the punched-out character.

In slower cases (and they sometimes go on for years), the symptoms, equivocal at first, become more and more significant as the disease proceeds. One leading symptom is *pain*—felt in a circumscribed space in the epigastrium, and often at the same time, or alternately, in the back, just below the shoulders. The pain begins immediately upon, or very soon after, the entrance of food into the stomach ; especially of food or drink which is hot or stimulating. It usually continues until the digested aliment has passed the pylorus ; or until vomiting puts an end to it. The pain is produced or aggravated by pressure, by exercise, curiously too, by mental anxiety, — mitigated by recumbency — and accompanied frequently by sour eructations.

Vomiting is another of the principal symptoms, — later commonly in its arrival than the pain ; occasional at first ; afterwards very frequent. Supposing an ulcer present, this is a very dangerous symptom. It tends to starve and weaken the patient, and so to promote the progress of the ulcer : it augments also the hazard of its suddenly breaking through.

The persistence of these symptoms, — which are symptoms of mere dyspepsia also may justly engender the suspicion of a gastric ulcer : and if, after they have existed for some time, copious hæmatemesis should supervene, the suspicion passes into something like certainty. Dr. Budd holds that if profuse vomiting of blood occurs in a person between the ages of eighteen and thirty, after a long continuance of pain in the stomach, extending into the back, with tenderness of the epigastrium, the pain and soreness being always brought on or increased by meals, with occasional sour eructations and occasional vomiting, with no great wasting or constitutional disturbance, no evidence that the orifices of the stomach are obstructed, and no tumour to be felt — hardly a doubt can remain that the disease is simple ulcer of the stomach.

Some of the last qualifications, and the limitation as to age, are introduced to exclude the only possible alternative of *cancerous* ulceration—of which I shall by and by have to speak.

Having achieved this point in the diagnosis, the ambition of still greater precision is natural and laudable. Dr. Budd thinks that when there is much tenderness of the epigastrium, and no pain in the back, the ulcer is most probably on the anterior face of the stomach. According to Dr. Brinton the decubitus may sometimes be a guide : the ulcer is most likely to occupy that part of the stomach which is uppermost when the patient is lying in his habitually easiest position.

The practical management of this perilous condition is delicate, but simple and obvious. When the symptoms are urgent, the patient should remain at rest ; and even keep himself in the recumbent posture. All food which is likely to create pain by its quality or by its temperature, or which has been found upon trial to give pain, should of course be forbidden. Tepid milk, alone, or thickened with biscuit-powder — containing as it does all the elements of nutrition — is probably the very best *kind* of food. The stomach must never be *distended* by a meal ; yet the strength and nourishment of the body require to be cherished and sustained. The food must therefore be taken in small quantities, and often ; a table-spoonful say, or two table-spoonfuls, every two hours. If the pain be severe, it may sometimes be appeased by counter-irritation ; the mustard poultice for example, or a stimulating liniment containing opium, applied to the epigastrium, or to the back. Bismuth, in doses of eight or ten grains, is often found serviceable ; it may sometimes be advantageously combined with five grains of the compound kino-powder : or from three to five grains of the compound soap-pill may be given from time to time. When there is hæmorrhage, ice swallowed in small quantities is both beneficial and grateful to the patient : and nutritive enemata may spare the stomach some of its work, and help to maintain his strength. If the bowels are sluggish, their action may be regulated by an aloetic or a colocynth pill.

These are the points to be kept in view. The detail must be left to the common-sense of the practitioner. And when I say this, I am forcibly reminded of a most striking and instructive case, beautifully told by the celebrated Dr. William Hunter, 'in the sixth volume of the *Medical Observations and Inquiries*. The perusal of that

history has afforded me hints upon which I have often acted with great advantage to my patients, and with some credit to myself, in treating chronic diseases of the stomach. As I doubt whether many of you would find immediate opportunity or leisure for referring to the narrative, and as I should spoil it by attempting to give you an abstract of it, I am tempted to read it here in Dr. Hunter's own words.

"Many years ago (he says) a gentleman came to me from the eastern part of the city, with his son, about eight or nine years old, to ask my advice for him. The complaint was great pain in the stomach, frequent and violent vomitings, great weakness, and wasting of flesh. I think I hardly ever saw a human creature more emaciated, or with a look more expressive of being near the end of all the miseries of life. The disorder was of some months' standing, and from the beginning to that time had been daily growing more desperate. He was at school when first taken ill, and concealed his disorder for some time; but growing much worse he was compelled to complain, and was brought home to be more carefully attended. From his sickly look, his total loss of appetite, besides what he said of the pain which he suffered, but especially from his vomiting up almost everything which he swallowed, it was evident that his disorder was very serious.

"Three of the most eminent physicians of that time attended him in succession: and tried a variety of medicines without the least good effect. They had all, as the father told me, after sufficient trial, given the patient up, having nothing further to propose. The last prescription was a pill of solid opium; for in the fluid state, though at first the opiate had staid some time upon his stomach, and brought a temporary relief, it failed at length, and like food, drink, and every medicine which had been given, was presently brought up again by vomiting. The opiate *pill* was therefore given in the hopes that it would elude the expulsive efforts of the stomach. It did so for a time; but after a little use, *that* likewise brought on vomiting: Then it was that his physician was consulted for the last time, who said that he had nothing further to propose.

"Though at first the boy professed that he could assign no cause for his complaint, being strictly interrogated by his father, if he had ever swallowed anything that could hurt his stomach, or receive any injury by a blow, or otherwise, he confessed that the usher in the school had grasped him by the waistcoat at the pit of the stomach, in a peevish fit, and shaken him rudely, for not having come up to the usher's expectation in a school-exercise. That though it was not very painful at the time, the disorder came on soon after. This account disposed the father to suspect that the rude grasp and shake had hurt the stomach. With that idea he brought him to me, as an anatomist, that an accurate examination might if possible discover the cause or nature of the disorder.

"He was stripped before the fire, and examined with attention in various situations and postures; but no fulness, hardness, or tumour whatever could be discovered; on the contrary, he appeared everywhere like a skeleton covered with a mere skin; and the abdomen was as flat, or rather as much drawn inwards, as if it had not contained half the usual quantity of bowels.

"Having received all the information that I could expect, and reflected some little time upon the case, I wished to speak with the father alone, in another room; and to give my patient some employment as well as refreshment, asked him to take a little milk in the mean time. But his father begged that taking anything into his stomach might be put off till he got home, because he was certain that it would make him sick; 'just before we set out (said he) I gave him a little milk; but he was sick, and brought it all up in the coach, before we had got many paces from the house.'

"In the adjacent room I said to the father, This case, sir, appears to me so desperate, that I could not tell you my thoughts before your son. I think it most probable, no doubt, that he will sink under it; I believe that no human sagacity or experience could pretend to ascertain the cause of his complaint: and without supposing a particular or specific cause, there is hardly anything to be *aimed at* in the way of a cure. Yet, dreadful as this language must be to your ear, I think you are not to be without hope. As we do not know the cause, it may happen to be of a temporary nature, and may of itself take a favourable turn; we see such wonderful changes every day, in cases that appear the most desperate, and especially in young people. In them the resources of nature are astonishing

"Then he asked me if I could communicate any rules or directions, for giving him a better chance of getting that cure from nature, which he saw he must despair of from art.

"I told him that there were two things which I would recommend. The first was not so important indeed, yet I thought it might be useful, and certainly could do no harm. It was to have his son well rubbed, for half an hour together, with warm oil and a warm hand, before a fire, over and all around his stomach, every morning and evening. The oil, perhaps, would do little more than make the friction harmless, as well as easy; and the friction would both sooth pain, and be a healthful exercise to a weak body.

"The second thing that I had to propose, I imagined to be of the utmost consequence. It was something which I had particularly attended to in the disorders of the stomach, especially vomitings. It was, carefully to avoid offending a very weak stomach, either with the quantity, or quality, of what is taken down; and yet to get enough retained for supporting life. I need not tell you, sir, said I, that your son cannot live long, without taking *some* nourishment; he must be supported to allow of any chance in his favour. You think that for some time he has kept nothing of what he swallowed; but a small part must have remained, else he could not have lived till now. Do you not think, then, that it would have been better for him if he had only taken the very small quantity which remained with him, and was converted to nourishment? It would have answered the end of supporting life as well, and perhaps have saved him such constant distress of being sick, and of vomiting. The nourishment which he takes should not only be in very small quantity at a time, but in quality the most inoffensive to a weak stomach that can be found. Milk is that kind of nourishment. It is what Providence has contrived for supporting animals in the most tender stage of life. Take your son home, and as soon as he has rested a little, give him *one* spoonful of milk. If he keeps it some time without sickness or vomiting, repeat the meal, and so on. If he vomits it, after a little rest, try him with a smaller quantity, viz., with a dessert, or even a teaspoonful. If he can but bear the smallest quantity, you will be sure of being able to give him nourishment. Let it be the sole business of one person to feed him. If you succeed in the beginning, persevere with great caution, and proceed very gradually to a greater quantity, and to *other* fluid food, especially to what his own fancy may invite him: such as smooth gruel, or panada, milk boiled with a little flour of wheat or rice; thin chocolate and milk; any broth without fat, or with a little jelly or rice or barley in it, &c., &c.

"We then went in to our patient again; and that he might be encouraged with hope, and act his part with resolution, I repeated the directions with an air of being confident of success. The plan was simple, and perfectly understood. They left me.

"I heard nothing of the case till, I believe, between two and three months after. His father came to me with a most joyful countenance, and with kind expressions of gratitude told me, that the plan had been pursued with scrupulous exactness, and with astonishing success; that his son had never vomited since I had seen him; that he was daily gaining flesh, and strength, and colour, and spirits, and now grown very importunate to have more substantial food. I recommended a change to be made by degrees. He recovered completely; and many years ago he was a healthy and a very strong young man."

In fulfilment of my promise I revert to the subject of *perforation* of the stomach.

There are three ways, exclusive of mechanical violence, in which such perforation may be effected. In each of the three the perforation proceeds from within outwards. All the coats of the stomach, as we have seen, may be penetrated in succession by a chronic ulcer. The direct contact of corrosive poisons may rapidly eat them through. They may be partially digested and destroyed by their own proper secretion, the gastric juice. Questions of much nicety and of grave importance present themselves, from time to time, respecting holes that are discovered in the stomach after death: medical questions, bearing upon pathology and therapeutics; legal questions, involving life and character in their solution. Perforation by disease, perforation by the gastric juice, are both liable to be mistaken, (and often have been mis-

taken) for evidence of murder or of suicide by poisoning. It is fit that you should have considered these points.

Now of ulcers of the stomach I have already told you all that I know: and it would be impossible for me, as well as out of place, to enter at large upon the topic of corrosive poisoning: that you will hear fully discussed by the Professor of Forensic Medicine. Perforation by the gastric juice demands a somewhat closer attention.

John Hunter, as you probably know, was the first to recognize and announce the remarkable fact that the stomach is capable, through the peculiar fluid furnished by itself, of digesting its own tissues. The dissolving power of the gastric juice survives for a while the vitality of the body, and acts as readily after death upon its parent flesh, as upon the food submitted to its influence during life. This discovery naturally excited great curiosity and interest. Hunter's observations were verified by several of his contemporaries or immediate successors; and hypotheses were soon framed to account for the supposed infrequency of the phenomenon. Dr. Adams thought that the stomach was soluble by the gastric juice, only when the death was general and complete as well as sudden; only, *i.e.*, when the stomach itself became instantly dead, and no organic vitality lingered in its tissues: and he took the continued fluidity of the blood, and the absence of the *rigor mortis*, as tests of such universal sudden death. He correctly supposed also that temperature was concerned in the matter. Mr. Allan Burns remarked that softening and perforation sometimes occurred in persons dead of chronic diseases; and he conceived that the gastric juice could exercise its solvent power, not only after being poured forth into the stomach, but also while still contained in its proper vessels. To this opinion he was led by finding perforation on the anterior face of the stomach. By degrees the simplicity of Hunter's doctrine was obscured and frittered away by hypothetical notions, propounded chiefly by continental writers, respecting the accessory operation of disease in producing these softenings. It was held that either the gastric juice, through some vice of the nervous system, was secreted of an unusually acrid and corrosive quality;—or that the mucous membrane of the stomach was rendered, by some previous morbid condition, more than commonly soluble in its own secretion after death. At length, the effect of the gastric juice was lost sight of altogether, and softening of the mucous membrane was ascribed to the sole agency of a kind of inflammation, or to faulty nutrition.

More than fifty years after the publication of Mr. Hunter's first paper on the subject in the *Philosophical Transactions*, Sir R. Carswell endeavoured to bring pathologists back to the truth, in a French essay, read before the Royal Academy of Medicine in Paris, of which a version is to be found in the thirty-fourth volume of the *Edinburgh Medical and Surgical Journal*. He therein shows that the action of the healthy gastric juice is sufficient to account for changes which—by Chaussier, Broussais, Louis, and others, abroad, and by Dr. John Gairdner in particular in this country, since the time of Hunter, as well as by Morgagni, and still earlier pathologists before that time,—had been attributed to the operation of disease. The whole subject has finally been surveyed and simplified by Dr. Budd, who has cleared up several of the difficulties that surrounded it, and explained some apparent anomalies, in the Croonian Lectures delivered before the College of Physicians in 1847. The substance of these lectures has since been published in his excellent book, already referred to, on diseases of the stomach.

For perforation of the stomach, or for softening of its tissues, by the gastric juice, three conditions must concur. In the first place the stomach must (of course) contain gastric juice; which appears to be secreted directly into its cavity, and never to be retained, as Allan Burns supposed, within its coats. Secondly, that fluid must possess its natural quality of acidity. Thirdly, a certain degree of heat is requisite for its solvent operation.

Now it has been proved by Spallanzani, and more clearly and fully by the interesting observations of Dr. Beaumont, to which I shall hereafter more particularly refer, that during the state of health, no gastric juice is secreted into the stomach, except under the stimulus of food, or of some mechanical irritation, applied to its interior.

Hence we perceive why it is that perforations of the stomach, of the kind in question, are most of all to be expected when a healthy person is suddenly killed by violence, soon after a meal, and while the process of digestion is in progress.

But instances do occasionally happen (Dr. Budd relates a very remarkable one) in which the same kind of perforation is met with, although no food had for some time before death been admitted into the stomach.

Dr. Budd believes the secretion of the gastric juice to be a reflex process; which he assimilates to, and illustrates by, the secretion of tears. Tears may be presently made to flow by direct mechanical irritation of the conjunctiva, or, indirectly, by pungent vapours acting upon the nostrils, or by certain feelings of the mind. In like manner the secretion of the gastric juice may, he conceives, be excited, not only by some stimulus applied immediately to the mucous surface of the stomach, but also under certain diseased conditions or injuries of distant organs, (as the brain, and lungs) and even by mental emotion. In this way he would explain the occurrence of perforation or of softening, after death by blows on the head, when no food had been recently introduced into the stomach; and after death by pulmonary consumption.

That more or less digestion of the tissues of the stomach after death is exceedingly common, is a fact which was well known to John Hunter, but which has been lost sight of by the majority of more recent observers. "There are few dead bodies" (he writes) "in which the stomach is not at its great end in some degree digested; and one who is acquainted with dissections can easily trace the gradations from the smallest to the greatest."

Dr. Budd points out circumstances which frequently interfere to prevent this effect of the gastric juice, by annulling one or both of the other conditions, just now mentioned.

The solvent property of the fluid is arrested whenever its acidity is neutralized by the admixture of an *alkali*. This has been fully proved by Spallanzani and others. The same is true of *alcohol*. But in the last moments of slowly ebbing life, medicines containing ammonia, and alcohol in some form or other, are very commonly indeed poured into the stomach. Moreover, if the gastric acid happen to be present in small quantity, "it may be neutralized, and thus rendered inert after death, by transudation of the alkaline serum of the blood."

Cruveilhier found softening of the fore part only of the stomach, in a person who had died of fever, with marked disorder of the brain. Allan Burns also records a case of perforation of the anterior of the stomach; the patient was anasarcaous. In both instances the stomach was empty; *i. e.*, "its surface was merely moistened by the gastric juice." Dr. Budd supposes that in the first of these cases, the blood, remaining fluid after death, gravitated to the lowest part of the organ, and there gave out its alkaline serum, whereby the small quantity of gastric acid collected in its fundus was rendered neutral and inert; and that, in the second case, the alkaline dropsical fluid, oozing through the coats of the stomach at its lowermost part, had the same effect.

Again, the gastric juice is solvent of those things whereof it is the natural menstruum, at a certain temperature only. Probably it is most active at or about the standard temperature of the body. Below 60° its digestive action is found to be feeble, or extinct. Softening therefore—and *à fortiori* perforation—are more likely to take place in summer than in winter; in warm weather than in cold; in a heated room than in the cool open air; and after some modes of dying, which imply a long retention of the vital warmth, than after others.

I have mentioned, for the sake of explaining them, certain exceptional cases, in which the front of the stomach was digested; but the rule is that the softening, which usually comprehends a considerable space, happens almost always at its largest end, and in its lowest part, where whatever fluid it may contain collects under the influence of gravity. If the surface be wrinkled into folds or ridges, the summits of those ridges may alone be dissolved. Sometimes the stomach, lying across the vertebral column, is partially supported by it, and two little pools, and two spots of softening, are formed, one of them to the right of the spine, towards the pylorus. Now and then the gastric juice passes out of the stomach into the œsophagus, or into the duodenum, and these parts exhibit traces of its action. And when actual perforation occurs, the chemical solution of the animal tissues sometimes extends further; and the organs immediately opposite to the aperture undergo the digestive process:—the

spleen, the intestines, the liver, the diaphragm, nay, after penetration of the diaphragm, even a portion of the lung.

These apertures produced by the gastric juice have soft and ragged edges, and are irregular in their size and outline. When the softening has stopped short of perforation, the mucous membrane looks and feels pulpy, like paste, or is completely dissolved and gone. The pulp varies in colour from brown to gray, according to the quantity of blood contained in the part. The blood-vessels that ramify over the softened portion are rendered black, or brown, and therefore conspicuous, by the effect of the acid on their contained blood; or, if they are empty, the surface is pale, and presents that uniform, semi-transparent, jelly-like aspect which, under the name of "gelatinous softening" has been erroneously spoken of as the result of disease.

The stomachs in which this agency of the gastric juice is discernible show no marks of putrefaction: there is no extrication of gas, nothing of the factor of gangrene; but their interior always exhales a peculiar acid odour, and litmus applied to the softened spots turns red.

Chronic ulcers, on the contrary, affect chiefly the lesser curvature of the stomach, and are commonly situate nearer the pyloric orifice than the cardiac: their margins are thickened by inflammation; or, if not thickened, the edge of the hole in the mucous membrane is smooth and regular. They are not necessarily associated with a sour smell, nor with acid reaction upon litmus paper.

Perforations of the stomach by corrosive poisons are discriminated from other perforations, by the specific chemical tests of the presence of those poisons; by the amount of disorganization which they have produced; by traces of their corrosive action upon other parts—in the mouth, in the fauces, in the œsophagus; by the violent symptoms which precede the fatal result of their operation; and (often) by the history and moral features of the case.

If you bear in mind the particulars that I have thus hastily brought together, they will, I trust, enable you to avoid wrong inferences, which you might otherwise be led to form concerning the morbid appearances and real conditions of the tissues of the stomach, laid open to your inspection after death.

[Acute gastritis is a disease of by no means unfrequent occurrence during infancy, and then often causes a softening of the mucous membrane of the stomach, to which much attention has of late years been directed by the observations of Cruveilhier, Louis, Laisné, Billard, and others; by several of whom it is described as a specific disease. It is to this particular lesion that we wish to direct especial attention on the present occasion, referring the reader for information on the subject of the inflammatory affections of the stomach generally, that occur during the early period of life, to the Editor's Treatise on the Diseases of Children.

The symptoms of the particular form of acute gastritis, to which we have reference, are very accurately described by Billard. The disease commences with the phenomena of a violent inflammation of the stomach; as tension of the epigastrium, which is painful to the touch; frequent vomiting, not only of the milk and drinks taken, but also of a green or yellow fluid; the vomiting occurring every moment, without any reference to the period when the child has taken food or drink. There is, sometimes, diarrhoea, varying in different subjects, and returning after having ceased for a day or two; the matters discharged from the bowels being often green, and similar to those brought up from the stomach by vomiting. The extremities are cold; the pulse is generally irregular; the countenance has a permanent expression of suffering, the face remaining furrowed, as if the infant were crying; the cry is expressive of pain; the respiration is interrupted, and the general agitation so great that the existence of a cerebral affection might be suspected. At the end of six, eight, or fifteen days, the patient sinks exhausted from the want of sleep, the constant vomiting, and pain. In very young infants the disease is attended with little or no fever.

Dr. Iselin, of Mühlheim, who had an opportunity of studying the disease during its extensive prevalence as an epidemic at Göttingen, gives the following description of its phenomena:

Previous to the attack, the child is often, for several days, unusually restless and fretful—finally, a decided febrile attack occurs, attended with a quick pulse, hot and dry skin, intense thirst, sleeplessness, and constant vomiting, increased upon food or

drink being taken into the stomach. To these symptoms is speedily added a copious diarrhoea—the dejections being, at first, of a greyish colour, and of some degree of consistence, but subsequently of a yellowish or greenish serum, decidedly acid. The evacuations are usually preceded by contortions of the countenance, indicative of pain, which are likewise induced by pressure on the abdomen. The latter is always much, often enormously distended, and its temperature, especially at the epigastrium, is often considerably elevated, while the extremities are cool, or even decidedly cold. The patient exhibits great prostration of strength, and a profuse partial perspiration soon breaks out, particularly about the head.

The disease varies in its duration—proving fatal, in some cases, within twenty-four hours, and in others, not until after a continuance of several days, or even weeks.

In the more violent cases, its onset is very sudden—and it is attended with frequent fainting, and an irregular and very quick pulse—the eyes and features are sunken—the body is bathed in a profuse perspiration. Convulsions, more or less severe, often attended with strabismus, sooner or later, occur; the face becomes of a bluish tint; the diarrhoea or vomiting, or both, soon become suspended; the accessions of fainting and convulsions become more frequent, and during one of these, death usually takes place.

The intumescence and augmented heat of the abdomen, particularly of the epigastric region, and the coldness of the extremities, are, according to Dr. Iselin, to be considered as among the most constant and characteristic symptoms of the disease. The agonized expression of countenance, and sunken appearance of the eyes, are likewise almost invariably present, even from its earliest stages.

The age at which this form of gastritis usually occurs is within the first year; it is not, however, necessarily restricted to this period of life.

The most constant lesion discovered after death is a softening of the mucous membrane of the stomach, and often of the small and great intestines; the membrane being reduced to a disorganized and gelatinous pulp; or, the softening may extend to all the tissues of the stomach, rendering them liable to be perforated by the slightest force. In the stomach these softenings occur, according to Baron, Billard, and Iselin, especially at the great curvature, seldom extending beyond the most depending parts. Distinct traces of inflammation are occasionally observed, surrounding the softened parts, and patches of inflammation often exist, also, in different portions of the intestinal canal, especially in the small intestines. The parietes of the stomach frequently present a serous infiltration.

Carswell, Burns, Gairdner, Hope, and several other pathologists, deny the connection in these cases, between the softening of the gastro-intestinal mucous membrane and inflammation, and maintain that, in general, it is to be viewed as a cadaveric phenomenon, resulting from the action of the gastric juice upon the tissues of the stomach; others, with Jæger, Zeller, and Camerer, refer it to a paralysis of the nerves of the stomach, with increased acidity of the gastric juices, by which the tissues of the organ are dissolved during the lifetime of the patient. A somewhat similar opinion is entertained by Laisné, Chaussier, Desbarreaux, Bernard, and others. Without denying that the softening observed after death in the stomachs of children may be, in many cases, strictly a cadaveric phenomenon, and that, in other cases, it may result, during the lifetime of the patient, from other causes than inflammation, we are, nevertheless, well convinced from the result of repeated and cautious observations, that the gelatinous softening so frequently met with in the stomach of those infants who die after exhibiting all the symptoms of acute gastritis, is invariably the effect of an intense inflammation, commencing in the mucous tissue of the organ.

Softening of the parietes of the stomach, as well as of the intestines, unquestionably often takes place previously to the death of the patient, in cases where it cannot be supposed to be the result of inflammation. Thus, we not unfrequently observe in infants brought up by the hand, or improperly fed subsequently to weaning, a loss of appetite, peevishness, great restlessness, and want of sleep; the tongue becomes coated with a layer of white or yellowish mucus; and in some instances aphthæ appear upon the parietes of the mouth, and the breath has usually a decidedly acid odour. There are a constant diarrhoea, and intense thirst. The diarrhoea, after a time, frequently diminishes, or entirely ceases—but soon returns again with increased violence—the discharges being a thin serous fluid of a yellow or greenish hue, and having a very

strong acid smell; great emaciation and exhaustion soon ensue; the face and extremities become cold; the pulse small and irregular; the respiration quick and short. The child utters continually a low piteous moan, or lies upon his back with the eyes fixed, glassy, and half closed. No pain or tenderness is indicated upon gentle pressure of the abdomen; the latter is, however, often greatly swollen and tympanitic. The child becomes more and more exhausted, and, finally, expires quietly, and without convulsions.

This train of symptoms, with slight variations, marks that form of disease described by Camerer, Pommer, Hergt, Romberg, Droste and others, as gastro-malacia, and in which the stomach, and often the intestines likewise, present a gelatinous softening of their parietes, to a greater or less extent, but without the slightest indication of inflammation. The softening appearing to depend upon a diminished cohesion of the tissues—the result probably of disordered or suspended nutrition.

Acute gastritis as it occurs in the infant, is under all circumstances, and throughout all its stages, difficult to manage, and but little under the control of remedies. At its very onset leeches to the epigastrium, followed by warm fomentations or soft emollient poultices, assiduously applied, will be found advantageous. Internally, minute doses of calomel will often remain upon the stomach and allay the excessive irritability of that organ. We have occasionally combined the calomel with the acetate of lead: one-fourth of a grain of the first with half a grain to a grain of the second, will, in a large number of instances, very speedily control the vomiting and purging, and afford us time to reduce the local inflammation by leeches to the epigastrium, followed by blisters, kept on for one or two hours, and then replaced by an emollient poultice. The thirst of the child should be allayed by small quantities of some bland mucilaginous fluid, given cold, and repeated at short intervals. Slightly astringent and bitter infusions are recommended by some practitioners during the period of convalescence, and we think that we have seen very decided benefit result at this period from the proto-carbonate of iron in moderate doses.—C.]

The stomach is very frequently the seat of specific malignant disease; of cancer in its various forms and denominations. The fatal nature of this complaint; the obscurity in which it is sometimes wrapped; the possibility of overlooking it altogether, or of confounding it with disease of a more innocent character, combine to invest it with peculiar interest.

Carcinoma of the stomach has sometimes no symptoms at all, or none which the most sagacious practitioner would refer to the organ affected. Not long since I saw, in consultation, an elderly clergyman, who complained of pains in his back, which were brought on or aggravated by certain movements of the body. His bowels were costive; and purgatives always relieved his pains. He was passing lithic acid gravel. The pains were felt in or near the renal region. Several years before he had suffered in a similar manner; and had then been cured by being cupped on the loins. What was the matter here? Was it lumbago? Was there a calculus in one of his kidneys? These were the best guesses that I could make. The eminent physician whom I met, and a surgeon of no less eminence, who had seen the patient previously, had not been able to attain any more exact diagnosis. Upon this gentleman's death, which occurred not long afterwards, his disorder was discovered to have been cancer of the stomach. Excepting slight sickness a day or two before he died, there had been no symptom to direct attention to that part.

A young woman came into the Middlesex Hospital, under one of my colleagues, with a pulsating tumour in her epigastrium. It was thought, at first, to be an aneurism, and the case attracted, on that account, a good deal of notice. But the tumour subsided very much after free purgation. This led some to suppose that it was formed by accumulated feces in the transverse colon. There was no sickness; nor indeed any one symptom referable to the stomach. She died. The tumour was cancerous; and in the stomach. Lying in front of the abdominal aorta, it had been lifted by its pulsations.

I was summoned to one of the hotels in Albemarle-street, to see a gentleman between forty and fifty years of age, who was on his way home from the Scottish Highlands, where he had been deer-stalking, and shooting grouse. He had been seized in the night with deadly faintness, very rapid breathing, and severe pain which

he referred to the sternum. I could detect no fault in his heart, or in his lungs. His epigastrium felt full and pulpy. The next night he had a similar paroxysm, in which he died. His body was examined by Mr. Paget. The lungs and heart were sound in structure. The large curvature of the stomach presented, throughout its whole extent, a mass of scirrhus lying beneath and among thick ridges of mucous membrane, with two or three deep patches of ulceration. Both the cardiac and the pyloric orifice were free from change.

This gentleman had gradually lost flesh and strength; but the only definite symptoms of which he had complained were sour eructations, and a total loss of appetite, and repugnance to take food.

Cases to the same effect are related by Dr. Seymour, in the *Medico-Chirurgical Transactions*; and by M. Andral, in his *Clinique Médicale*.

But even when the stomach is the organ pointed out, by the symptoms, as the probable seat of the malady, those symptoms fail, often, to indicate with any certainty its nature. The effects of the carcinomatous disease exhibit no uniformity. The ingestion of food is apt to produce great distress; but differently in different cases: sometimes as soon as the food is swallowed; sometimes not for an hour or two afterwards. Some cases are attended with much pain; some with none at all. One patient vomits continually; another has little or no vomiting from first to last.

Can these differences be in any way accounted for? Partly they may. By analyzing case after case, we approximate to a knowledge of their causes. But this knowledge is yet far from being complete.

One circumstance that has a considerable influence upon the symptoms, is the *situation* of the disease. In respect to this point there are certain general rules which are for the most part true. Still we can speak of them only as applicable *on the average*; they are not absolute or infallible.

The rules I mean are these:—

1st. That there is more suffering, *ceteris paribus*, when the cancerous disease is situate at, or very near, either extremity or orifice of the stomach, than when it occupies the intermediate parts: whether in the greater, or in the lesser curvature.

2d. That when the cardia, and its immediate neighbourhood, is the part solely or principally diseased, the food and drink find a hindrance in passing the stomach; but being once there, the distress is over. The symptoms are very like those of strictures of the œsophagus. The morsel reaches the bottom of that tube, and there causes uneasiness, till at length it is brought up again through the mouth, or passes gradually in the natural direction.

3d. That when, on the other hand, the disease is limited to the pyloric end of the stomach, the food enters that bag readily enough, and remains there for a certain time; then uneasy sensations arise, and the imperfectly digested meal is apt to be rejected by vomiting.

It is the difficulty of passing the *doorway* in these cases, that gives rise to the principal suffering: the difficulty of getting into, or the difficulty of getting out of, the stomach. But when the disease is confined to the intermediate space, no such difficulty occurs: and therefore little or no pain.

You must expect, I say, to meet with individual variations from these rules. A remarkable example of such variation was presented by one of my hospital patients, in the year 1837. I have the notes of that case before me, which I will read *short*.

Simon Ailes, aged thirty-six, admitted March 14. His main complaint was of pain in the epigastrium, always present, but augmented, in frequent paroxysms, to an extreme degree of severity. At first, pressure gave him some relief. The pain was most violent an hour or two after he ate. He was troubled also with flatulence, and with sour eructations. Occasionally a clear tasteless fluid, looking like water, rose into his mouth. His bowels were costive.

At this time his countenance was natural and placid; but it gradually assumed that pinched and anxious expression, and that peculiar yellowish hue, which are so significant of organic visceral disease. He wasted fast. At length the epigastrium became tender as well as painful: but no tumour, except the left edge of the liver, could be felt there. He died on the 11th of May, about eight months from the commencement of the pain. A week before his death he vomited some dark, grumous, offensive fluid, evidently containing blood. With this exception he had no vomiting.

Many remedies were tried, which I do not specify, for none of them gave him any sensible or continued relief.

In the smaller curvature of the stomach we found a ragged, sloughy surface, as big as the palm of one's hand, and extending to within half an inch from the pylorus. A section of this diseased portion exhibited the characters of true scirrhus: a white and hard mass, nearly half an inch across at its thickest part. The mucous membrane of the duodenum was congested, and dark coloured. The rest of the intestines were healthy except the rectum, which was surrounded, towards the anus, by scirrhus and thickened areolar tissue, intermixed in laminæ. The gut itself was not affected.

The diseased stomach was removed, and examined by Mr. Kiernan, who found, upon careful dissection, that the trunk of the gastric branch of the par vagum ran directly into, and was lost in, the scirrhus mass. This sufficiently accounted for the dreadful sufferings of the patient.

And I am here reminded that, with regard to the structural alteration itself, there are some circumstances well worth attending to.

Andral places all these organic affections of the stomach in the class of chronic gastritis. But it is clear that he is wrong: and you will perceive at once that it is of immense importance to recognize the specific disease from the mere result of common inflammation.

But though cancer is not, in any case, a mere product of common inflammation; neither is all that is called cancer really such. Specimens of morbid texture, misnamed scirrhus of the pylorus, are not uncommon in anatomical museums. I show you some from our own; not so denominated, however. The correct labelling would be *hypertrophy*. You may perceive that the areolar and the muscular tissues near the pylorus, are very much thickened. A section of the thickened parts presents an appearance somewhat like horn; and is crossed by whitish lines that run nearly parallel to each other. The morbid structure is quite definite and uniform; and very dissimilar, in that respect, to the irregular masses of scirrhus, and to the amorphous deposits of encephaloid cancer. Neither does it at all resemble that of the colloid variety of carcinoma. Changes of this kind are liable to occur in the muscular tissue of this, as of other organs, whenever a permanent obstacle is opposed to the onward progress of the contents of the hollow viscus. The impediment may have been originally produced by inflammatory thickening of the textures composing the pylorus; and then the hypertrophy may, in a certain sense, be accounted a consequence of inflammation. To that extent alone is M. Andral right. He has unquestionably pushed his theory on this subject too far. Whatever narrows the pyloric orifice leads to increased effort of the propelling muscle, and to augmentation of its bulk and power. Now cancer itself, situated at, or close upon, the pylorus, may impede the exit of the digested aliment; and then it causes a gradual hypertrophy of the muscular coat. In these cases there is a mixture of the two changes; of the cancerous growth, with the muscular hypertrophy: and this is one reason why they have been confounded together. Here are several preparations, exhibiting true cancer of the stomach. At the bottom of each bottle may be seen a sort of whitish powder or sediment, consisting of some of the matters peculiar to cancer. This fact has been pointed out to me by Mr. Kiernan in the numerous specimens contained in his private collection. But there is no such deposit when the hypertrophy is not combined with malignant disease.

To those who are conversant with its revelations, the microscope, in equivocal cases, becomes a valuable diagnostic test.

It has long been thought and asserted, that the cancer of the stomach is not so apt to be attended, as cancer of other parts, with a disposition to present itself in various organs of the body at the same time, or

FIG. 108.

Scirrhus Pylori. At the diseased part, the walls of the stomach are extremely thickened, and of a whitish colour.

in succession. Now I believe—and I am glad to add the weight of Mr. Kiernan's authority to my statement—that this is not really so. Cancer is a constitutional affection: or, if local and solitary in the outset, is prone to disseminate itself. The error has arisen out of that confounding of one morbid condition with another, against which I have been warning you. Instances are not at all uncommon of thickening of the areolar and mucous tissues about the pylorus, producing first a mechanical impediment to the passage of the food, then more energetic muscular efforts towards its expulsion from the stomach, and at last hypertrophy of the muscular tunic. In these cases, you do not find cancer in other organs: because, in fact, there is no cancer in the stomach.

You may say that as both forms of disease are alike fatal, it signifies nothing whether there be really cancer or not. But it is always satisfactory to clear away an apparent anomaly, and to show that it has no real existence. Besides, you know with how much anxiety the relatives of the dead inquire concerning these matters. That cancer “runs in families” is well understood even by the public. An example of this hereditary disposition has just occurred to me in practice (1853). A patient of mine, a barrister, forty-eight years old, has sunk under scirrhus disease involving the omentum, and extending into all the folds of the peritoneum. This gentleman's mother died of malignant disease of the leg, where it commenced as a small wart. Her brother died of cancer of the lungs which penetrated the sternum, and sprouted out upon the chest. And this brother's wife, who was his cousin also, fell a victim to some form of cancer. The distinctions which I have been pointing out are surely worth learning, if they do no more than enable us to comfort the minds of survivors, and to relieve them from the apprehension that they also may be doomed or likely to become the subjects of this horrible disorder.

Notwithstanding what I have now been saying, it must be allowed that genuine cancer of the stomach is accompanied less frequently than some other modes of carcinomatous disease, by cancer elsewhere. In fact cancer of the stomach is most often of the scirrhus variety, which until it softens is not so readily disseminated as the others, and which is apt to prove fatal before it softens.

When primary cancer of the stomach is of the encephaloid kind, — or when, being scirrhus, it begins to grow soft,—its secondary manifestation occurs chiefly, as I told you on a former occasion, in the *liver*: the reason being that the veins of the stomach communicate with the general system not directly, but through the hepatic capillary system. Cancer of the colloid or gelatiniform species, with which also the stomach is liable to be affected, spreads mainly, when it spreads at all, by inoculation of parts of the body that happen to be in contact with it.

But to return to the *symptoms* of carcinoma of the stomach. In some cases, I say, the food is rejected by vomiting; in some cases it is not. Now it has been argued that this difference depends upon the condition of the pyloric outlet; whether it be free and open, or contracted and shut. The explanation is more plausible than sound.

It is not strictly consistent with facts. Vomiting of the food has been an urgent symptom, when there was no mechanical bar to its passage into the duodenum. The pylorus is a sphincter muscle, of which the natural and habitual state is that of contraction. It yields, however, in health, to the pressure of the digested aliment, which is driven forwards by the muscular fibres that surround, and compress by their action, *the pyloric end of the stomach*. If there be a mechanical impediment, that affords a sufficient reason why the food should be thrown up again. But sometimes, I repeat, the orifice is wide open, and yet the food is rejected: and it is rejected because the disease so involves the pyloric end of the stomach, that the propelling force cannot be exercised.

When there is a mechanical obstacle, the disposition to hypertrophy of the muscular coat is conservative. But in feeble and delicate persons, the baffled muscles may never acquire strength enough to overcome the impediment; and then the very opposite condition is apt to take place: the coats all become very thin; meal after meal is retained; the stomach is enormously distended, and relieves itself now and then, at distant intervals, by copious vomiting; until at last it is unequal to that effort, and the patient dies.

Sometimes the sickness and vomiting are urgent even when the stomach contains no food: and the matters rejected are of various character and appearance. They

often resemble coffee-grounds, and consist, no doubt, of altered blood. Vomiting of this kind is a very pregnant sign of *organic* mischief in the stomach.

Emaciation is another ugly circumstance in these cases; and forms a strong ground of presumption that the symptoms depend upon structural disease. Yet it is not a uniform consequence, even of malignant disorganization of the stomach. Napoleon Bonaparte was very fat when he died. His omentum is described as having been "remarkably fat:" and "the fat was upwards of an inch thick upon his sternum, and one inch and a half upon his abdomen."

The existence of a palpable tumour strengthens the unfavourable diagnosis. But this is far from being a constant phenomenon. It is not even pathognomonic when it does occur. The diseased head of the pancreas has been mistaken for a thickened pylorus. The stomach is liable also to be dragged much out of its place; and then a thickened pylorus may be mistaken for something else. Sometimes the form of the stomach may be distinctly traced. In the person of a medical practitioner who died lately in this neighbourhood, the shape of the organ, its occasional peristaltic motions, and the irregular and hardened pylorus, were plainly to be felt. They might indeed almost be *seen*, in the hollow and attenuated abdomen. When a tumour is ascertained to belong to the stomach, it indicates disease of the pylorus rather than of the cardia.

In equivocal cases the diagnosis may sometimes be aided by remembering the facts that cancer of the stomach rarely happens before the age of 35; that it is steadily progressive, and generally kills the patient within 12 or 15 months; and that it is attended with a peculiar sallowness of complexion, and gradual wasting of the flesh: whereas chronic ulceration of the stomach may arise at any period of life, and may continue to exist for 5, 10, or even 20 years together, without much constitutional disturbance, or marked diminution of the general bulk and strength.

It is a curious feature in these malignant diseases of the stomach, that the symptoms sometimes remit, in a remarkable manner; so as to excite a hope in the mind of the patient, and in that of his medical attendant, that the nature of the malady had been mistaken, and that recovery is about to take place. But the truce is not for long. Frightful disorganization is at length produced, ragged ulceration, perforation of the coats of the stomach, adhesion to the parts adjacent, which thus are constituted adventitious walls;—and inevitable death at last.

The treatment of this dreadful complaint can only be palliative. If there be pain, we are driven, sooner or later, to opium. Anodyne enemata have often as good an effect in relieving the pain as opium given by the mouth; and they have this advantage, that their constipating properties are more easily obviated than when that drug is put into the stomach. Nutritive injections are proper when food taken through the natural channel is not retained.

Other palliative measures may be aimed at particular symptoms: of these I propose to speak when I come to the symptoms and remedies of *dyspepsia*.

LECTURE LXIX.

Hæmorrhage from the Stomach: sometimes from a large vessel, usually capillary. Idiopathic Hæmatemesis. Vicarious Hæmatemesis; Hæmatemesis from Gastric disease or injury; from disease in other organs. Melæna. Hæmatemesis from a morbid state of the blood. General phenomena of Hæmatemesis. Diagnosis. Treatment.

HÆMORRHAGE from the stomach, to which I wish next to direct your attention, is of much more frequent occurrence than acute gastritis. It is a complaint, or a symptom, that presents several points of interest and importance. I use the phrase "hæmorrhage from the stomach," rather than the single term "hæmatemesis,"

because that term, signifying strictly a *vomiting* of blood, does not necessarily imply hæmorrhage *from the stomach*; nor, indeed, does it always accompany such hæmorrhage, although it is one of its most common and most striking symptoms.

What I have so frequently mentioned in respect of hæmorrhages from the mucous membranes generally, viz., that the efflux of the blood is seldom owing to the rupture of a large blood-vessel, holds true in this. It can rarely happen that any vein or artery belonging to the stomach is divided or laid open by accidental injury, so as to pour forth its blood. When hæmorrhage does proceed from one or more of the larger blood-vessels, the opening by which the blood escapes is commonly the result of chronic ulceration; such as I spoke of yesterday. Sometimes hæmatemesis is a consequence of the erosion of a blood-vessel by an ulcer in the *duodenum*; such as I mentioned before as being apt to follow severe and extensive burns. But hæmorrhage from the stomach, and from the alimentary canal generally, is far more commonly what we have agreed to call *capillary hæmorrhage*.

Now this kind of hæmorrhage happens under various circumstances; and is attended with different degrees of danger. 1. The bleeding may be idiopathic. 2. It may be vicarious of some other habitual hæmorrhage. 3. It may depend upon disease or injury of the stomach itself. 4. It may be the consequence of disease situate elsewhere, and producing, mechanically, a plethora of the veins of the stomach. 5. It may result from a morbid condition of the blood, and form one symptom of a more general disease; as in the passive hæmorrhages of purpura and sea-scurvy. Each of these varieties requires a short notice.

1. Hæmorrhage strictly *idiopathic*—i. e. independent of any apparent change of texture, whether in the surface itself, or in any part obviously capable of influencing its blood-vessels—is as rare, I believe, from the mucous membrane of the *stomach*, as from that of the *lungs*. I have never seen, nor do I recollect to have read of, any instance of hæmatemesis analogous to the *epistaxis* which is so common in children and young persons; and which affords the most familiar example of idiopathic hæmorrhage.

2. But hæmorrhage from the stomach, occurring in connection with other constitutional hæmorrhages, or in their stead—and above all, occurring *vicariously* of menstruation—is *abundantly* common. It is the most common indeed of all the species of hæmorrhage *by deviation*. I told you, in a former lecture, that patients will sometimes menstruate for years together through the lungs; without any apparent injury to their general health. More commonly still do they menstruate through the stomach. I will mention one concise but singular example of this which I had from Dr. Latham, and which came within his own knowledge. A young woman became the subject of hæmatemesis, recurring at monthly periods, about the age of fourteen. She had never menstruated. This continued until she married and, in due time, fell with child. Thereupon, the hæmatemesis ceased. She brought forth and suckled her infant. During lactation the hæmorrhage did not recur. It came on again soon after she ceased to nurse the child; no regular menstruation by the uterus having ever happened. This was the woman's own account, and there appeared no reason to question its accuracy.

Gastric hæmorrhage of this kind, vicarious of regular menstruation, is not generally thought to have any tendency to shorten the existence of those who are afflicted with it. Cullen states broadly that this species of hæmatemesis is hardly ever a dangerous disorder: and this is true. Yet it is not so *entirely* free from peril as to preclude the necessity of *some* caution and qualification in stating the prognosis. The exhaustion from the mere loss of blood is sometimes so great as to create serious alarm for the patient's safety. And Mr. North has recorded (in the *London Medical and Physical Journal*) two instances in which suppressed menstruation was followed by repeated and at length *fatal* hæmatemesis. In neither of these women was the health seriously deranged; nor, previously to the hæmorrhage, did there exist debility, or any other symptom calculated to excite the apprehension of danger. In fact, in both of these cases, a strongly favourable prognosis was given by experienced physicians a very short time only before the fatal event.

3. Gastric capillary hæmorrhage is often a consequence of *disease or injury of the stomach itself*. It is sometimes one of the earliest declaratory symptoms of scirrhus or cancer of that organ—occurring long prior to ulceration. Hæmatemesis attends

also, very commonly, the *ultimate* stages of that fatal disease : and then it may be owing to the erosion of some vessel of notable magnitude, in the course of the process of disorganization, as in the examples already spoken of : or (what I believe is far more common) it may result from a kind of general oozing from the ulcerating surface. Blood is often vomited soon after the reception of strongly irritant poisons into the stomach. I show you again Dr. Roupell's plate, representing the crimson surface of a portion of the stomach of a dog which had been killed shortly after the administration of a dose of alcohol. The intense congestion thus produced is doubtless *active* congestion ; congestion belonging to inordinate *arterial* action. Pushed a degree further, such congestion passes into hæmorrhage.

4. On the other hand, intense *passive* congestion — congestion arising from the detention of blood in the *veins* by some mechanical obstacle to its progress—is a very common source of gastric hæmorrhage. Hæmatemesis is therefore an occasional symptom of obstructive disease of the heart. Much more frequently, however, it depends upon abdominal changes. The hæmorrhage is symptomatic of disease situate, not in the stomach itself, but elsewhere. And the viscera, with the diseases or morbid conditions of which, bleeding from the stomach is most often connected, are the liver and the spleen.

All this is well known : and it is easy to see, from the peculiar construction of the venous apparatus in the abdomen, how disease of one or both of these viscera may produce mechanical congestion of the submucous capillary tissue ; and how that congestion may be relieved, under certain circumstances, by the effusion of serous fluid on the one or the other surface, constituting ascites or diarrhœa, as the case may be ; or under *other* circumstances, not perhaps easily discriminated or well understood, by the extravasation of the collected blood itself. It would be superfluous to describe the peculiar distribution and functions of the vessels which return the main portion of the venous blood from the stomach and intestines towards the heart. It seems to me highly probable that one at least of the offices of the *spleen* is to provide a receptacle or reservoir for this blood, when its free passage through the portal vessels is temporarily obstructed. It then becomes a sort of safety valve (if such an illustration be allowable), which obviates the danger that might otherwise arise to more vital parts from any great or sudden disturbance of the venous circulation. The stress of the congestion is continually felt in the submucous capillary system ; and the hæmorrhage which is apt in such cases to occur from the loaded membrane, receives a simple solution upon principles almost purely mechanical. Nay, the very circumstances which lead to the effusion of the blood from the *mucous* surface on the one side, rather than from the *serous* on the other, may perhaps be themselves susceptible of mechanical explanation.

Gastric hæmorrhage, symptomatic of hepatic disease, is chiefly to be looked for in those morbid conditions of the liver which imply obstruction of the portal vein and of its ramifications. We are not surprised, therefore, to find it coincident, often, with a contracted and shrunken state of that organ. The state of the spleen, on the contrary, for reasons that must be obvious to you, is uniformly, in the cases that we are now considering, a state of *enlargement*. And the augmentation of bulk is not so much to be ascribed to disease inherent in its proper texture, as to distension by the mere quantity of blood which it holds. The internal structure of the spleen furnishes a credible presumption in favour of that view of one of its uses to which I just now alluded ; and this structure, and this presumed function, when considered together, throw a strong light upon some of the pathological relations of the spleen, which well deserve attention.

Numerous instances are on record of hæmatemesis going along with evident enlargement of the spleen ; and in some of them that organ has been observed to diminish in bulk, in proportion as blood was poured out by the stomach. If I am not greatly mistaken, I have more than once seen this myself. In such cases the tumid condition of the spleen may be regarded as an evidence of venous obstruction *elsewhere* ; and as depending, sometimes at least, upon disease of a less striking and prominent character in the liver, impeding the progress of the blood through the vena portæ. Of this kind would seem to have been a case related by Morgagni, wherein, after repeated attacks of hæmatemesis, under which the patient sank at last, the spleen was found to weigh four pounds, and to be gorged with dark blood : while the liver was pale

and exsanguine. Frank gives the history of a patient, who had vomitings of blood, and whose spleen, taken from the body after death, weighed sixteen pounds: the ordinary weight of the spleen in a healthy adult being from eight to ten ounces. In Latour's work on *Hæmorrhage*, which is remarkable for the number of examples it contains, collected from various sources, and amounting to nearly a thousand, several instances are detailed of this combination of splenic enlargement with hæmatemesis. One of these occurred in the person of a friend of his, who had been living in a malarious district, and who had laboured for nearly two years under obstinate intermittent fever. This was followed by an immense enlargement of the spleen—a great *ague-cake*—which came to occupy almost the whole of the abdomen. Latour's experience enabled him to predict that hæmatemesis would probably supervene upon this condition of the spleen; and, accordingly, one night he was called in a hurry to his friend, and found that he had vomited an enormous quantity of clotted blood. A great deal passed away through the bowels also. The hæmorrhage recurred from time to time, till in the course of a month the spleen was so far reduced in bulk, that it could no longer be felt in the belly: and the patient lived, and enjoyed good health, for twenty-five years afterwards.

It is necessary, therefore, in marking the connexion which frequently subsists between hæmatemesis and enlargement of the spleen, to guard ourselves against concluding that these two circumstances hold always the relation of cause and effect. In many such cases, probably in most of them, they are simply concurrent effects of one common cause; and that cause is chiefly to be sought in such morbid conditions of the liver—or of other parts within the abdomen—as are competent to produce a considerable impediment to the free transmission of blood through the system of the *vena portæ*.

When gastric hæmorrhage results from hepatic obstruction, there is almost always *intestinal* hæmorrhage also. At any rate there are almost always black alvine evacuations, like tar or dark paint. This form of disease has therefore been called *melæna*. The ancients supposed that the unnatural stools consisted of black *bile*.

Hæmorrhage from the stomach, independent of *disease* in that or in any other part, sometimes happens in the advanced periods of utero-gestation. Yet, though it does not result in these cases from disease, it is difficult to class it among idiopathic hæmorrhages. The want of periodical recurrence, and the absence of the hæmorrhage during the *earlier* months of pregnancy, are circumstances which sufficiently refute the old notion, that this form of hæmatemesis depends also upon the suspension of the catamenia. It is caused, no doubt, by the pressure of the gravid uterus, which impedes mechanically the venous circulation in the abdomen.

5. Gastric hæmorrhage, resulting from *changes in the blood* itself, occurs in scurvy, in purpura hæmorrhagica, and in the yellow fever. Being merely a symptom in these cases, it requires no separate consideration here.

When a *large* quantity of blood is poured into the stomach, whatever may have been its source, it appears to have a nauseating and emetic effect. At least the blood ejected in hæmatemesis is almost always considerable in amount. The vomiting may, for aught I know, be dependent on the mere distension of the stomach, which appears to be tolerant of the presence of the blood, up to a certain point, but no further. A small quantity may, doubtless, pass all of it onwards through the pylorus, after undergoing, more or less completely, the process of digestion in the stomach; and a *portion* of the blood pursues that course in most instances. But when it is vomited, it comes up in large quantities, usually of a dark colour, and more or less coagulated. Sometimes the coagula have evidently been moulded in the stomach; and sometimes clots are thrown up, partially deprived of the colouring matter of the blood, and resembling the fibrinous polypi so often met with in the cavities of the heart. Of course the degree of the coagulation of the blood, and of its separation into serum and crassamentum, will depend upon the time that it remains in the stomach; and this again would seem to bear a proportion to the rate of its effusion.

The blood that is vomited is almost always of a dark colour; while that which is coughed up is most frequently florid and bright. Why is this? We are told that the blood which comes from the lungs is rendered florid by the admixture of atmospheric air. But this is not the whole of the matter. Neither can we say that the

dark hue of the blood ejected in hæmatemesis is always, or solely, due to some morbid alteration effected in that fluid while yet circulating in its proper vessels. There is another cause, which, till of late years, was much overlooked, but which frequently changes the colour and appearance of the blood *after* it has been extravasated into the stomach; and that in so great a degree as sometimes to render doubtful, or to disguise altogether, the real nature of the fluid vomited. I mean the chemical agency of the gastric acid. The effect of acids in blackening the blood out of the body is well known; and it is somewhat singular that the ascertained existence of an acid secretion in the stomach, varying in quantity at different times and under different circumstances, was not sooner applied in explanation of the dark colour of the blood, and its occasional blackness, when vomited. The degree of blackness will be in proportion to the relative quantity of acid which it meets with in the stomach, and the intimacy of the admixture. Sometimes the blood is clotted and not very much altered in colour; sometimes it is grumous, brown, of a chocolate tint, or like coffee-grounds. This generally denotes the existence of *organic disease*; and the appearance of the blood is probably modified in some degree by the morbid process that leads to its effusion. There is good reason for believing that in the *black vomit* of the yellow fever, the colour of the blood undergoes alteration, even while it is yet circulating through the blood-vessels; but that the black appearance of the matter vomited is in great part owing to the chemical action of the gastric acid, may be inferred from the fact, that the fluid so discharged is always (so I am informed) intensely acid. Andral has described an effusion of black liquid into the stomach, as an example of *melanosis*. He states at the same time that an accurate analysis of the liquid showed its composition to be very nearly the same with that of the blood. May we not suspect that this inky fluid really consisted of blood that had been blackened, subsequently to its extravasation, by the acid with which it mixed in the stomach? Upon the same principle may be explained the dark brown, or almost black, colour of the spots which are sometimes seen (I presume when there has been a great superabundance of acid) in the substance of the mucous membrane of the stomach, or even beneath it; and which also have been set down as melanotic. They are so like, in all circumstances, except in the single particular of colour, to the crimson spots which are obviously formed by minute extravasations of blood in the same parts, that we can scarcely refer them to any other source. The slate-coloured patches, which I spoke of yesterday as being vestiges of chronic gastritis, depend likewise upon the blackening effect of the gastric acid upon the congested surface. We have the same dark colour of the effused blood, in many cases, when it is poured out in the intestines. Here, of course, its colour is not referable to the gastric juice; but it is blackened by some of the intestinal gases; probably by the sulphuretted hydrogen for example, or by the carbonic acid that enters into their composition.

There can be no doubt that this gastric acid, when intense in strength, or copious in quantity, is capable of changing the colour of the blood, after death, even while it is contained in the sub-mucous blood-vessels. In these cases it must be conveyed to the blood by imbibition. And the very same thing takes place when strong acids are introduced into the stomach from without. When, for instance, the sulphuric acid, or what is perhaps more to our present purpose, the vegetable oxalic acid, has been taken as a poison, it has the effect of blackening, and, as it were charring the blood, with which the membrane becomes loaded in consequence of the irritation produced by the poison. It does this when no destruction of the mucous membrane has been produced.

It is but justice to observe, that the credit of having been the first to perceive, and to explain, this cause of the blackened state of the blood, while yet remaining in its proper vessels, is due to Sir Robert Carswell.

When blood is ejected through the œsophagus and mouth, we have demonstrative evidence of the existence of *hæmorrhage*; and the *diagnosis* of *hæmatemesis* may appear to be so simple as to admit of neither mistake nor doubt. The diagnosis of *hæmorrhage from the stomach*, however, is really oftentimes difficult and obscure, and to be established by presumptive evidence alone.

In the first place, bleeding may take place from the mucous membrane of the stomach, and no hæmatemesis ensue, especially when the blood is poured forth in

small quantities, and slowly. In these cases the blood becomes visible only in the stools, where it may not be looked for, and where, if seen, it may not always be recognized, in consequence of the changes which it has undergone during its passage through the intestinal canal. And even supposing that its presence is detected in the alvine evacuations, it will remain uncertain in what part of that long canal it was effused. The hæmorrhage may even be profuse, and the patient may die, without any escape of the blood externally. There is a case related by Frank, in which death took place from hæmorrhage of the stomach without hæmatemesis; and both the stomach and the intestines were found distended by an enormous coagulum of blood which had assumed their form.

Even when the blood is ejected by the mouth, the exercise of some care and sagacity is occasionally, though not always, required, in order to determine the part from which it was originally poured out.

Thus blood may be swallowed, and afterwards vomited: and so we may have hæmatemesis without hæmorrhage from the stomach; just as we may have hæmorrhage from the stomach without hæmatemesis. There are cases of slow bleeding from the lungs, the fauces, the mouth, or the nasal cavities, where the blood, collecting in the pharynx, provokes, from time to time, an instinctive and involuntary act of deglutition; and thus is gradually accumulated in the stomach up to that point at which the organ becomes impatient of its contents, and ejects them by vomiting. This is very apt to happen during sleep, and especially to young children: and as the blood, *when vomited*, is coagulated, and in considerable quantity, it is scarcely possible to conclude, from its mere appearance, that it has proceeded from any other source than the stomach itself. If, however, we mistake such cases, our error is likely to produce much needless alarm, and to lead us to unnecessary activity in treating them. We are assisted towards forming a right judgment (when our attention happens to be directed to this source of fallacy), partly by the general history and symptoms, and partly by an examination of the mouth, fauces, and nostrils, to ascertain whether any coagula, or other marks of hæmorrhage, are visible on the mucous membrane belonging to those parts.

But blood may be swallowed knowingly and purposely, by impostors, and afterwards vomited. Hæmatemesis is one of the complaints which have frequently been feigned; either for the sake of avoiding some imminent punishment, or distasteful service; or with the view of exciting compassion, and of profiting by the contributions of the charitable and the credulous; or sometimes from a kind of wilful perversity, akin to insanity. In treatises on forensic medicine, you will generally find reference made to an instance of this kind recorded by Sauvages, in his *Nosology*. A young girl, who was anxious at all hazards to escape the constraints of a convent, pretended that she was suffering from violent hæmatemesis. In fact she did, for several days in succession, vomit large quantities of blood in the presence of the physician who had been summoned to her assistance. It was afterwards discovered that on each of those days she had swallowed blood which had been secretly conveyed to her from the neighbouring shambles. A case of precisely the same kind occurred (as I was informed by a gentleman who witnessed it) in the Bristol Infirmary some years ago. A girl had been long a patient there, labouring (as was supposed) under hæmatemesis; but it was at length discovered that she was a malingerer. She was in the habit of assisting the nurses in their work; and this afforded her opportunities — of which she availed herself — of drinking the blood which had been drawn from the veins of other patients: and this blood she afterwards vomited.

And even where no fraud is attempted, nor any blood swallowed, it occasionally becomes a nice matter to determine the origin of the hæmorrhage, when blood is ejected in large quantities from the mouth: to decide, namely, whether the blood has come originally from the *lungs* or from the *stomach*. In copious hæmoptysis, the blood issues from the mouth in gushes, as it does in hæmatemesis; and the reflux of the blood into the pharynx, the tickling sensation it there produces, and the cough (which we know, even when the expectoration is not of blood, frequently excites retching); these causes, acting singly, or together, occasion sometimes a convulsive contraction of the muscles of the thorax, which *looks like* the effort of vomiting: they often, indeed, give rise to actual vomiting. On the other hand, in sudden and profuse hæmatemesis, the irritation caused by the blood

as it passes over the upper part of the larynx, is apt to provoke a paroxysm of choking cough.

Now, when I was speaking, some lectures back, of hæmoptysis, I promised that I would point out the means of distinguishing it from hæmatemesis, when I came to the consideration of the latter complaint. I have now therefore to redeem my promise.

However equivocal certain cases may be at first sight, we may generally guide ourselves to a correct decision by a careful investigation of the circumstances that *precede, accompany, and follow* the hæmorrhage. *Vomiting* of blood is commonly preceded by a sensation of weight and uneasiness in the epigastrium; and by nausea. Hæmatemesis is also, more frequently than hæmoptysis, ushered in by paleness of the face, dimness of vision, and an approach to syncope, or even actual fainting. These symptoms are not to be regarded (I apprehend) as premonitory of the hæmorrhage, although they have been so considered by some; they are rather a sign that it has already taken place; and yet they *are* preliminary of the hæmatemesis. Occurring before the blood comes up, they cannot be ascribed to alarm at the *sight* of it. On the other hand, *hæmoptysis* is wont to be announced by dyspnœa, cough, tickling in the throat, and a sensation as if of *bubbling* within the thorax. Most commonly too, before the expulsion of much blood from the lungs, some sputa are *coughed up*, composed more or less of that fluid. The symptoms that usually *succeed* the hæmorrhage in either case, afford equally valuable assistance to our judgment, in cases that might otherwise be doubtful. Generally copious hæmoptysis goes on, in a succession of mouthfuls, for some time; whereas there is, mostly, only one access of full vomiting. At any rate, at the close of abundant pulmonary hæmorrhage, the patient manifestly *coughs up*, and expectorates, smaller quantities of blood; while we usually may observe that, a few hours after hæmatemesis has occurred, slight griping pains come on in the abdomen, and a portion of blood is got rid of from the bowels.

Other questions, often of much importance in regard to the ultimate diagnosis, when the blood is traceable with certainty to the stomach, are, whether it be idiopathic, if, indeed, it *ever* be so: whether it be supplemental of some other discharge: whether it depend on disease of the stomach itself; of one, or more, of the contiguous viscera; or of the system at large. Certainly, in a very great majority of cases, gastric hæmorrhage is symptomatic; and the nature and seat of the disease of which the bleeding is a symptom, may, in many instances, be determined without much difficulty. That which depends upon *incipient* cancer of the stomach, while it is by no means of rare occurrence, is also, (I think) more frequently than other forms of hæmorrhage from that organ, obscure. It must be obvious to you, and therefore I need not dwell upon this part of the subject, that a little attention to the symptoms and past history of the patient will usually suffice to elucidate the nature of the case, where hæmatemesis supervenes immediately upon the introduction of corrosive poisons, or within a certain interval after they have been swallowed: where it depends upon the bursting of a large aneurism: where it breaks forth among other symptoms of scurvy or purpura: where it is the result of an *advanced* stage of cancer of the stomach: where it accompanies organic disease of the liver, spleen, or heart: where it occurs as a symptom of yellow fever: where it takes the place of suppressed or imperfect menstruation: or where it is occasioned by the pressure of the gravid uterus. In all these cases, there is, ordinarily, no room for mistaking the one disease for the other; or for regarding the hæmorrhage as idiopathic.

With respect to the *treatment* that should be adopted in cases of hæmorrhage from the stomach, it must be apparent, from what has just been said of the many different morbid conditions upon which it may depend, or with which it may be essentially connected, that remedies are, in most cases, rather to be directed against the disease of which the hæmatemesis is a symptom, than against that symptom itself. But sometimes we are obliged to treat the symptom: either because we are not certain of the exact nature of its cause; or because the condition out of which it springs is not within our reach.

Cases of *melæna* (I have told you what is meant by that term) require hard purging; and many patients recover thoroughly under that rough mode of treatment. You may prescribe five grains of calomel every night, and a black dose every morning, till the stools lose their pitchy colour. Do not be afraid of purging your patients

in such cases. If they are curable at all, that is the way to cure them. I have pursued that plan with perfect success, even with patients whom the previous hæmorrhages had blanched, and whose pulse was feeble and irregular. You may sustain them, at the same time, by a full allowance of nourishing broths. The portal system is drained and unburdened by this active depletion. And if there be no irremediable change of texture in the liver, the recurrence of the hæmorrhage may often, by a proper regulation of the habits and diet, be averted. The ancients had learned by observation the efficacy of treatment of this kind; but they used a different form of medicine, and purged away the *atra bilis* with hellebore.

It is plain that for melæna, dependent on mechanical congestion, *styptic* substances would be worse than useless. They are more adapted to those cases (could we but surely distinguish them) in which the hæmorrhage proceeds from a bleeding vessel. This is indeed the mode whereby we often succeed in stanching external hæmorrhages; namely, by applying astringents to the very part. Dr. Budd very properly lays great stress upon *prolonged fasting* in such cases. Similar means may be employed when hæmatemesis, of a purely passive character, depends upon some modification of the circulating blood. There is one remedy which is thought to have a sort of specific effect upon hæmorrhages of the gastro-intestinal canal: I mean the oil of turpentine, given in small doses; from twenty minims to half a drachm every four or six hours. I cannot say that I have had much experience of it. Of course the patient must be kept cool and quiet; whatever he drinks he should drink cold: even ice is often both grateful and effectual. If ordinary measures fail, recourse may be had to the acetate of lead; or even to the quack medicine, Ruspini's styptic. Not that I think you will often find the latter expedient successful, when more rational treatment has failed; but in obstinate and dangerous cases it ought to be tried. The Gallic acid, in solution, would however be more legitimate. If, with the hæmatemesis, there be any fever, it may be proper and necessary to abstract blood from a vein, and to employ refrigerant substances as remedies; and if, with or without much fever, there be tenderness at the epigastrium, leeches, or a blister, should be applied. In cases where the catamenia desert their natural channel, and seek an outlet through the mucous membrane of the stomach, it will be well, while means are taken to discourage the hæmatemesis, as iced drinks and so forth, to endeavour to solicit the discharge towards its right direction. And we often succeed in this object, by placing leeches upon the groins of these patients immediately before the period when the vicarious menstruation is expected; and by putting their feet at the same time into hot water; or even by laying them in a warm hip bath.

LECTURE LXX.

Dyspepsia. Physiology of digestion. Symptoms of Dyspepsia. Treatment and Prevention, Dietetic and Medicinal.

It is my intention to appropriate this evening's lecture to a cursory account of *dyspepsia*; by which I mean some evident derangement in the natural process of digesting and assimilating our food; and more especially, a faulty performance of the functions of the *stomach*. Indigestion is the prevailing malady of civilized life. We are more often consulted about the disorders that belong to eating and drinking, than perhaps about any others: and I know of no medical topic concerning which there is afloat, both within and beyond the profession, so much ignorant dogmatism and quackery.

Cullen, in his definition of dyspepsia, enumerates the various symptoms, by the occurrence of more or fewer of which, that complaint is most commonly manifested. "Anorexia, nausea, vomitus, inflatio, ructus, ruminatio, cardialgia, gastrodynia:—

pauciora saltem vel plura horum simul concurrentia, plerumque cum alvo adstrictâ, et sine alio vel ventriculi ipsius, vel aliarum partium, morbo."

The variety in the actual presence and combination of these symptoms is very great: and any attempt to give a perfect or complete history of dyspepsia in these lectures is quite out of the question. But I will endeavour to draw such a general outline of the disorder as may assist and direct your observation of it hereafter.

I shall first take a brief view of the *pathology* of indigestion, so far as it is understood: and to make this intelligible, it will be necessary to interweave something of the *physiology* of the subject. To these preliminary considerations, I shall add a short comment upon the several symptoms of dyspepsia, enumerated in Cullen's definition: and lastly, I shall state what I know respecting the means of curing, and of preventing, this familiar disorder.

The conditions of healthy digestion are these: that the food should be masticated, mixed with saliva, and swallowed into the stomach: that in the stomach it should be reduced into a semi-fluid consistence and converted into a uniform pulp, called chyme: that the chyme should be transmitted through the pylorus into the duodenum, and there mixed with the bile, the pancreatic secretion, and the intestinal mucus; in consequence, as it would seem, of which admixture, the whole is separated into two parts, viz. the chyle or the nutritive portion of the food, now in a fit state to be taken up by the veins, or by the lacteals which open upon the mucous surface of the intestines, and to be carried by them into the blood; and the excrementitious portion, which at length is conveyed out of the body.

The food is dissolved and transformed, in the stomach, by the chemical agency of the *gastric juice*. This is a secretion peculiar to the stomach. All that need be stated of it here—almost all indeed that is known—is, first, that it oozes forth in minute drops from the mucous surface, but only when food (or some solid substance) is present in the stomach; secondly, that it is always *acid*; and thirdly, that under various disturbing influences and conditions, it is liable to be excessive, or else deficient, in quantity. To its acid, together with a peculiar albuminous principle which has been named *pepsin*, it appears to owe its solvent power.

The food, having arrived in the stomach, is moved about, by a sort of churning or revolving movement, and mixed with the gastric juice, and gradually changed into chyme: which also is acid. Finally, the chyme is propelled by degrees into the duodenum by the pressure of the transverse band of muscular fibres which embraces the pyloric extremity of the stomach. The time in which the whole operation is completed varies from two to four or five hours.

Liquids introduced into the stomach disappear much more speedily; either by direct absorption, or through the pylorus.

All this we know, not from mere speculation on the anatomy and usages of the organ, but from actual observation. An American physician had, for several months in succession, the singular privilege of looking, whenever he pleased, into a healthy human stomach, and of watching its condition, its movements, and its contents, during the process of digestion. A young Canadian had a portion of the skin, muscles, and ribs, of the left side of the body blown away in a gun-shot wound, which laid open the stomach also. He recovered from this frightful injury with a permanent aperture in the side, communicating directly with the stomach. Through this loop-hole Dr. Beaumont was allowed to introduce various articles of food: and to withdraw from time to time the gastric secretions; and the aliment, in the different stages of its digestion. He has published a very interesting account of these experiments, which have set at rest some points in the physiology of the stomach that were previously uncertain. I shall embody his deductions in what I have further to say on the subject.

In order that digestion may be perfect and easy, it is requisite that the food be in a state of minute division. This object is attained by *mastication*. In like manner the chemist first *triticates* a solid, when he desires to facilitate its solution in the proper menstruum. A weak dyspeptic stomach acts slowly, or not at all, on solid lumps and tough masses of food. The delayed morsels undergo spontaneous changes, promoted by the mere warmth and moisture of the stomach: gases are extricated: acids are formed: perhaps the half-digested mass is at length expelled by vomiting; or it passes undissolved into the duodenum, and becomes a source of irritation and disturbance during the whole of its journey through the intestines. Here then we have one com-

mon cause of dyspepsia; and an easy and obvious preventive. Dyspeptic persons should not eat in a hurry, as busy men, and studious and solitary men, are apt to eat. They are to be cautioned against *bolting* their food: it must be well ground in the mill that nature has provided for that purpose. I am not at all sure that the increased longevity of modern generations is not, in some degree, attributable to the capability of chewing their food which the skill of the dentist prolongs to persons far advanced in life.

There are certain things upon which the gastric juice has no power. The green colouring matter of certain vegetables; the husks of seeds; the rinds of many fruits. You may perhaps have observed that dried currants and the pips of apples, swallowed entire, reappear, unchanged, among the egesta. Whatever passes the stomach untouched by the gastric liquor, passes undissolved through the whole of the alimentary canal; provoking disorder sometimes in its transit; forming sometimes a nucleus for intestinal concretions. These substances are therefore unfit for a weak stomach. When the digestive powers are active, and the bowels slow, they may perhaps occasionally be even useful. Thus brown bread—*i. e.* the indigestible bran, or tegument of the kernel of wheat—stimulates the peristaltic motions of the intestines, and averts, in certain persons, the necessity of more direct purgatives. Unbruised mustard-seed, once so much in vogue, owed much of whatever virtue it possessed to this principle. But if these intractable substances fail to excite the proper action of the bowels, they are apt to accumulate, and to lay the foundation of serious disease.

Indigestible matters, to which the pylorus refuses a passage, may remain in the stomach, and disturb its functions, for days, or even sometimes for weeks, together. If we could ascertain their presence, an emetic would be the remedy. And sooner or later vomiting is set up, and the offending substance is expelled. I lately saw a mass of hard curd—a small cream cheese in respect of consistence—which was thrown up after several days of severe gastric pain and disorder. The relief was immediate and complete. The patient had been taking large quantities of cream with his tea and coffee. In another person, a similar fit of indigestion terminated in the ejection of a mass of snuff. This is no unusual source of derangement of the stomach among those who use lavishly that nasty luxury.

The essential change which the chyme undergoes after leaving the stomach, appears to consist in its separation into two parts: namely, into chyle, which is taken up by the lacteals; and into excrement, which is discharged from the body. Any undissolved portions of the food become attached to this last part. We do not know exactly what is the function or agency of the pancreatic liquor; it has probably something to do with the absorption of fat: but with regard to the bile our knowledge is somewhat more definite. The acid developed in the stomach combines in the duodenum with the alkali of the bile, and is more or less neutralized. Dr. Prout conjectures that in a healthy state of the organs it is entirely neutralized. Bile is, moreover, the natural stimulus of the intestines: when its secretion is stopped, or its passage into the duodenum prevented, digestion and assimilation may go on, but the bowels are usually sluggish. This hepatic secretion has doubtless other important uses; but with these we are not at present concerned. It is pretty evident that the state of the biliary functions can have no direct influence in the production of mere indigestion. When the constituents of the bile are imperfectly eliminated from the blood, various parts of the body may suffer detriment. And when the functions of the stomach and the functions of the liver are both disordered, it *may be* that the former organ sympathizes indirectly with the morbid state of the latter: or it *may be* that one and the same cause operates in producing the derangement of both organs.

Let us now review the symptoms of dyspepsia which are mentioned in Cullen's definition. The first of these is *anorexia*: want of the natural appetite. Sometimes this is almost the only symptom observable. The patient is warned, by loss of appetite, not to take too much food; he refrains instinctively from certain kinds of food; or he feels perhaps absolute repugnance and disgust at the very thought of eating. Various have been the speculations respecting the immediate cause of hunger. It has been ascribed to the action of the gastric juice upon the surface of the empty stomach. But during health the gastric juice is never present in an otherwise empty stomach. Neither can the appetite depend upon contraction of the muscular fibres of the stomach; for the empty stomach, during health, is always contracted upon

itself. No doubt the sensation of hunger, like all other sensations, arises from some particular condition of the *nerves* of the part. It returns periodically, acknowledging in this respect the influence of habit. It is sensibly affected by agencies which operate upon and through the nervous system. The receipt of a piece of bad news will destroy, in a moment, the keenest appetite.

Sometimes there is no anorexia. The appetite may even be morbidly craving and ravenous; or capricious and uncertain.

When defect of appetite is the only symptom, it may be remedied, often, by the employment of bitters, or of the mineral acids, taken twice or thrice daily, for some time together. It would be out of place for me to speak in detail of particular medicines of this kind: it is enough if I indicate quina, columbo, gentian, quassia; the dilute sulphuric and nitric acids; or a mixture of the nitric and muriatic.

Nausea—vomitus. These are, in some instances, the most distressing results and signs of the dyspepsia. Sometimes nausea comes on soon after the food is swallowed. Sometimes there is no nausea; but after the lapse of a certain period, an hour or two generally, the food is rejected by vomiting. The matters thus thrown up are most frequently sour. Not seldom they are mixed also with bile, especially if the retching have been violent, or long continued; and then the patient is apt to ascribe the whole of his complaint to "an overflow of bile," although in fact the secretions of the liver have nothing whatever to do with it; the appearance of bile, in the fluids ejected from the stomach, proceeding from an inverted action of the duodenum. The effort of vomiting, however induced, will, if often repeated, be attended with the expulsion of yellow bile. I have more than once referred you, for an illustration of this fact, to the phenomena of sea-sickness. The fallacy I now point out has been one cause of the notion that is prevalent among patients, and the public—and not unfrequently perhaps among practitioners—that indigestion very commonly depends upon a disordered state of the biliary organs.

The vomiting which occurs in dyspepsia is often connected with a morbid irritability of the stomach; and it is sometimes a very troublesome symptom to treat. The carbonic acid has certainly a marked effect in allaying it, in many cases. We give it, as you know, in the effervescing saline draught, made with the carbonate of potash, or of soda, and lemon-juice. Sometimes the mineral acids answer better. Sometimes, on the other hand, alkalies—the liquor potassæ for example, or lime-water—are more effectual. In these latter cases we may presume that there is a morbid acidity of the stomach. A few drops of chloroform swallowed in water sometimes answer well. Small doses of opium are occasionally successful when other means fail. Opiates thrown into the rectum—opium plasters to the epigastrium—blisters to the same part: these are measures which you will sometimes have to try one after another. There are two special remedies which have been greatly extolled for their virtue in abating sickness: the hydrocyanic acid is one of them; creasote is the other. The hydrocyanic acid I have found exceedingly useful in obstinate cases. It may be given alone—or mixed with the effervescing draught—or combined with a few grains of the sesquicarbonate of soda. The creasote has disappointed me oftener than it has answered my hopes from it. Yet it has a decided influence in checking some forms of nausea; and it is the more likely to succeed, in proportion as the condition of the stomach is remote from inflammation.

But after all, the grand principle on which to treat chronic vomiting—not dependent upon disease in other parts, as the head, the kidney, or the uterus—is that laid down by Dr. William Hunter; of reducing the *quantity* of food to that amount, whatever it may be, which the stomach is able and willing to retain, and making its *quality* as bland and nutritious as possible. The most satisfactory case which I have had to treat upon this principle occurred some years ago, in the person of one of my hospital patients. She was brought out of Kent by her father. She had been under the care of several medical men, one of whom had been a pupil at the hospital, and recommended her as a proper patient for admission there. Her age was sixteen. She and her father both agreed in the same story; viz., that she constantly vomited her meals; the food generally coming up again immediately after it was swallowed, and never remaining longer in her stomach than ten minutes. The vomiting was described as being easy; and was neither preceded nor accompanied by nausea.

She had been ill for four years: ever since a severe attack of scarlet fever. At

first she vomited her meals now and then—three or four times a week—but the vomiting gradually became more and more frequent; and at the time of her admission she had vomited after *every* meal, for three months in succession. She had grown considerably in the four years; and was tolerably plump; and looked healthy; and the catamenia had begun to appear, though scantily, in the same period: but they had been altogether suspended for a year.

It was clear that a good deal of her food must have remained: and, bearing William Hunter's case in mind, I directed that she should have a very small quantity of roast meat for dinner, and a coffee cup of milk occasionally during the day; and no other food. I prescribed also some pills, consisting of aloes and soap, to act moderately on the bowels. I expected to have been obliged still further to limit her food: but she never vomited again, from that time. This distressful and protracted disorder, after long and fruitless treatment previously, yielded thus at once and easily to very simple means.

Inflatio—ructus. Flatulence, and belching. The gas that produces these symptoms is sometimes extricated from undigested food detained in the stomach, and in a state of fermentation, or of simple putrefactive change; sometimes secreted, apparently, by the stomach itself; for the flatulence comes on when the stomach is empty of food. It is apt to arise, in dyspeptic persons, if a meal happen to be delayed beyond the accustomed hour. Patients complain grievously of these symptoms, and accuse the “wind in their stomachs” as being at once the essence and the cause of all their complaints. They ask for medicines to get rid of the wind; and its escape may indeed be promoted by warm aromatics, and carminatives, as they are called; the relief thus afforded to the distended stomach being so sudden, and for the time so complete, that the sufferer ascribes to the medicine, *vim carminis*, the power of a charm. One of the most effectual and popular of these carminatives is peppermint-water. A due regulation of the periods for taking food will often suffice to obviate the flatulence that belongs to emptiness. That which follows eating may, in many cases, be prevented, by swallowing, immediately before the meal, five or six grains of the extract of rhubarb, with or without a grain of cayenne pepper: or still more certainly, according to my experience, by the nitro-muriatic acid, taken in small doses, half an hour, or an hour, before the food. When the belching is attended with the odour and flavour of rotten eggs—in other words when the gas evolved is sulphuretted hydrogen—it results from decomposition of the contents of the stomach. Flatulence from this cause may sometimes be prevented or subdued by charcoal, or by creasote, which, like the gastric juice itself, are powerful antiseptics. But this condition is commonly an accidental and transitory condition, and its best cure is an emetic. If the ascending wind brings into the throat and mouth a portion of the solid contents of the stomach, the patient is said to *ruminate*. The regurgitated matters are often intensely acid; and then an alkali may remedy the existing flatulence; a tea-spoonful of *sal volatile*, for example; or ten grains of the carbonate of soda.

Indigestion is, in many instances, attended with scarcely any *pain*; while in others the pain is very tormenting. Cullen speaks of it under the terms *cardialgia*: and *gastrodynia*. Cardialgia is that less violent and more permanent uneasiness which in popular language is called *heart-burn*. Gastrodynia is that more severe, and usually more transient pain, which is commonly denominated *spasm* or *cramp* of the stomach.

Dr. Abercrombie has some useful practical observations in respect to pain of the stomach. He speaks of it as occurring under four different forms; and I am able to bear witness to the reality of the distinctions that he has drawn. A still nicer discrimination of the varieties of stomach distress has been made by my friend Dr. Budd. In the first place, some persons suffer pain, occasionally, when the stomach is empty, even when there is no flatulence; and they are comforted and relieved by taking food. A clergyman of my acquaintance, who used to be much harassed by gastric pain of this kind recurring several times daily, and who had tried a round of drugs in vain, found by accident that it was appeased at once upon his eating a small biscuit. He therefore carries about with him always a supply of this easy remedy. It is reasonable to suppose that the pain in such cases depends upon some degree of acrimony of the fluids of the stomach itself. It often yields readily to alkalies, or to absorbent medicines. A tea-spoonful of the aromatic spirit of ammonia in a wine-glass of camphor

julep, or half a drachm of magnesia, will still the whole uneasiness sometimes in a moment, as if by magic.

Dr. Budd notes these further characteristics of this sort of pain; that it is accompanied by slowness of the pulse, and coldness of the surface of the body; that the recumbent posture helps it away; and that the hydrocyanic acid is a very successful remedy for it.

A second form of pain in the stomach is when it occurs *immediately* after taking food, and continues during the whole process of digestion, or until vomiting ensues, which gives instant ease. In such cases we have reason to suspect the existence of chronic inflammation, or of ulceration, or of some undue sensibility of the mucous membrane of the stomach. The suitable remedies are such as I spoke of in the last lecture. I might have mentioned a form of medicine which Dr. James Johnson found especially serviceable against this morbid sensibility; I mean the nitrate of silver, in small doses.

When uneasiness rather than pain occurs presently after a meal, with a sensation of weight at the pit of the stomach, and indisposition to bodily or mental exertion, we may infer that the work of digestion is slow and difficult, in consequence of a too scanty secretion of the gastric juice. For this form of dyspepsia those remedies are the most proper which are believed to promote the secretions of the stomach; ipecacuanha in small doses, or rhubarb, before the meal; or condiments taken with it, such as salt, mustard, cayenne pepper.

In the third species of painful disorder of the stomach the pain does not begin till from two to four hours after a meal, but continues for several hours. This is a very common form of complaint. Dr. Abercrombie is of opinion that the pain is seated in the duodenum, and connected with inflammatory action, or with morbid sensitiveness of the mucous lining of that bowel. He says it is frequently accompanied by pain and tenderness of the right hypochondrium; and that the liver is often blamed when it really is not in fault. The last remark I well believe; but I am not so easily persuaded that the pain is duodenal. I believe it depends upon acidity in the *primæ viæ*. It has been ascertained by several chemists, that the acid which is present in the gastric juice is the muriatic. Dr. Prout holds that the source of this muriatic acid is the common salt which exists in the blood, and that the decomposition of this salt is owing to the immediate agency of some modification of electricity; and he conceives that the principal digestive organs represent a kind of galvanic apparatus, of which the mucous membrane of the stomach and intestinal canal may be considered as the acid or positive pole, while the hepatic system is the alkaline or negative pole. However this may be, it is certain that the muriatic acid contained in the stomach is often in excess: other acids are also found there—the acetic, and more especially the lactic; and when the food, now converted into chyme, passes into the duodenum, the remaining superfluous acid teases the stomach. I think this explanation of the cause of the pain is a more probable one than Dr. Abercrombie's, because you may generally mitigate or remove the pain by introducing an alkali into the stomach, whereby the acid is neutralized; even the swallowing a cup of warm tea, by which the acid is diluted or washed away, often stops the pain. And I have, in numerous instances, succeeded in *preventing* the recurrence of this pain by directing the patient to take a small quantity of alkali, in some aromatic water, immediately after his dinner. According to Dr. Abercrombie's theory the pain ought not to be so immediately allayed by these remedies; and, since the food is gradually propelled into the duodenum as it is digested, the pain should begin, I think (supposing him right), earlier than it does. Dr. Abercrombie has found nothing of more general utility in these cases than the sulphate of iron, combined with one grain of aloes, and five grains of aromatic powder, taken three times a day. He praises lime-water also, and small opiates, and a combination of bismuth and rhubarb. Bismuth is believed to restrain undue secretion, and to exercise a sedative influence upon the stomach. Whatever may be its *modus operandi*, I am sure that it is a very effectual remedy for some kinds of gastric distress.

Cases now and then occur in which this pain, succeeding a meal, and the deposit of lithates in the urine, would seem to indicate the propriety of an alkaline treatment, but which really are more benefited by the mineral acids. In such cases the microscope detects oxalate of lime in octohedral crystals mixed with the lithate of ammonia, or of soda

Pain in the stomach occurs in a fourth form, coming on at uncertain intervals in most violent paroxysms, and properly call *gastrodynia*. It is often accompanied by a sensation of distension, much anxiety, and extreme restlessness. In females it is frequently combined with hysterical symptoms. This form Dr. Abererombie supposes to depend upon over distension of the stomach; and it may be so; certainly great quantities of the air are sometimes extricated; and the pain is not confined to the stomach, but shoots through to the back and between the shoulders. I suspect that the pain is sometimes neuralgic. It is often very intractable: occasionally it yields to carminatives; to a few drops, for instance, of cajeput oil suspended by means of mucilage in some aromatic water. Dr. Abererombie states that he has observed the most effectual relief in such cases to have been obtained from exciting a brisk action of the bowels by means of a strong purgative enema. He makes this practical remark, which is worth attending to. From the facility with which such affections often yield to the remedy just mentioned, it appears not improbable that the pain may be sometimes situated in the arch of the colon. Wherever its seat may be, I know that it is frequently removed by a mustard poultice laid upon the epigastrium. Opium also is of eminent use in many of these cases; and bismuth; and cordials: but I have seen more rapid and decided relief afforded by the prussic acid than by anything else; and the cure so wrought is often permanent. It does not bring ease in all cases, nor is it a medicine that is any particular favourite of mine, yet its good effect is in some instances so striking, that if this were its only virtue I should esteem the hydrocyanic acid a most valuable remedial agent.

You will meet sometimes with what is called *spasm* of the stomach (and I suppose it is such) in gouty people; who are then said to have gout in the stomach. The pain comes on in sudden and severe paroxysms; and is removable in general by laudanum and stimulants, brandy for example; or by the mustard poultice. On these cases, however, we look with jealousy and apprehension. In some instances the attack is really inflammatory, and would then be aggravated by a stimulant treatment.

There is another modification of uneasiness and disorder of the stomach, of which the distinguishing characteristic is a burning sensation in the epigastrium, followed by the vomiting, or rather the eructation of a thin watery liquid, resembling saliva, sometimes sourish, but usually insipid and tasteless, and often described by the patients themselves as being cold. This is what Cullen calls *pyrosis*, the *water-brash*. It is a disorder much more frequent in the lower ranks of society than in the upper: and among women than among men. It is very common in Scotland, and is there ascribed to the large employment of farinaceous substances as food, and especially of oatmeal. But it is said to be still more prevalent in Lapland: and it is not at all uncommon in Wales, and in various parts of England, where the diet used is chiefly vegetable. Dr. Cullen, who saw a great deal of this disease, says that its paroxysms "usually come on in the morning and forenoon, when the stomach is empty. The first symptom of it is a pain at the pit of the stomach, with a sense of constriction, as if the stomach were drawn towards the back. The pain is increased by raising the body into an erect posture, and therefore the body is bended forward. The pain is often very severe; and after continuing for some time, it brings on an eructation of a thin watery fluid in considerable quantity." Such is Cullen's description of *pyrosis*. He states that the complaint often occurs without other evidence of dyspepsia: but this is not consistent with the experience of subsequent observers. It is a symptom sometimes of organic disease of the stomach. In one remarkable case of *pyrosis* which I saw, and in which not less than three pints of this thin tasteless liquid was brought up every day, the stomach, after death, was found to all appearance healthy; but it had been pressed upon by an enormous liver. I mention these facts that you may not suppose *pyrosis* to be always, as Cullen has described it, a substantive and idiopathic malady.

Dr. Budd supposes that the ejected fluid, when insipid and alkaline, comes, not from the stomach itself, but from the salivary and other glands in the mouth and pharynx, and that its secretion is provoked by the uneasy sensations of the stomach. When the fluid has an acid taste, we may be pretty sure that a part of it at least is furnished by the stomach.

When *pyrosis* is not caused by organic disease in the stomach or in the liver, it will yield in general to opium, and especially to opium in combination with astringents.

The *pulvis kino compositus* of the Pharmacopœia is an admirable remedy for it. But we often have to contend with this difficulty, that the bowels, in cases of pyrosis, are apt to be confined, and that the opium tends to aggravate this unnatural condition; so that it becomes necessary to administer some aperient daily while the kino and opium are given: the watery extract of aloes, or the confection of senna, or the compound colocynth pill.

I scarcely need say that when the disorder has arisen under the use of innutritious or unwholesome food, the adoption of a more varied and generous diet, including a sufficient proportion of meat, is essential to the permanent success of any remedy.

One more form of stomach disorder I have still to bring before you. Like the last, it is attended with vomiting and characterized by the nature of the matters vomited. It is one of the acquisitions of modern diagnosis. In the year 1842, Mr. Goodsir, observing signs of fermentation in the fluids cast up from day to day by one of his patients, examined them in the expectation of finding some minute algæ which are known to accompany that process. To his surprise, however, a new form of vegetable life presented itself. He discovered multitudes of small flat bodies, having a rectangular outline, and a slightly oblong shape, divided into four similar portions by cross lines, and thus somewhat resembling little packets tied lengthwise and across by a string. These bodies he therefore named *sarcinæ*. Each of the four portions is similarly divided by fainter markings, in the manner of the diagram which I here show you. 

Instances of the same kind of disorder were soon after noticed and recorded by Mr. Busk, Dr. Todd, Dr. Bence Jones, Dr. Wm. Jenner, and Dr. Budd, who has devoted a lecture to this interesting subject.

The fluids vomited in these cases have a faint acid smell like that of fermenting wort; and it is obvious that they are themselves fermenting. After standing a few hours, they become covered with a thick, brownish, yeast-like froth, and they deposit a brown flaky sediment. In the frothy head, and in the flaky deposit are to be seen great numbers of *sarcinæ*, together with the *torulæ* proper to yeast. The fluid itself is always acid; or if not so, it contains no *sarcinæ*. *Sarcinæ* appear in the alvine excretions also.

Most generally the vomiting is copious, and sometimes it is enormous in amount, so that the stomach must have been vastly distended. It often takes place in the morning, after a night spent in distress from a sense of burning and distension in the epigastrium, and a feeling of bubbling or fermentation there. These painful sensations are relieved by the emptying of the stomach.

Vomiting of this kind is usually, if not always, indicative of some structural and incurable disease of the stomach; such disease as hinders the onward passage of its contents through the pyloric opening: any narrowing of that orifice, whether from cancer or from any other cause. Dr. Budd believes the disease to consist primarily and essentially in some organic change which prevents the stomach from completely or readily emptying itself, and which causes a secretion from the coats of the stomach capable, when mixed with the food, of undergoing or of exciting a fermentative process; and that the development of the *sarcinæ* bears to this fermentative process, or to some stage of it, the same relation as the development of *torulæ* bears to simple alcoholic fermentation.

The evolution of carbonic acid gas, and the formation of acetic acid, attending this process, produce heartburn, flatulence, and painful distensions; symptoms which alkalis may alleviate. But the most appropriate useful remedies are those which tend to prevent the process of fermentation. Of these, common salt, creasote, and the sulphite of soda have been found the most serviceable. They are all antiseptic. Salt, and creasote in the form of a pill, may be taken with the meals. The sulphite of soda owes its efficacy to its ready decomposition by almost any vegetable acid, this decomposition setting free sulphurous acid, which has great power in preventing the acetous fermentation. The sulphite may be administered soon after the meal, or when the fermenting process is commencing, in doses varying from a quarter of a drachm to a drachm, dissolved in water. This remedy, the most effectual in relieving a disorder which is probably always incurable, was introduced into practice by Dr. William Jenner.

Costiveness is a very frequent concomitant of dyspepsia, as Cullen's definition affirms

(plerumque cum alvo adstrictâ). And this sluggish state of the bowels often aggravates, if it do not produce, the dyspepsia. At any rate the defective powers and uneasy sensations of the stomach are rectified, in many instances, by measures which promote the regular and healthy evacuation of the intestines. Without professing to go into detail in this matter, I may state that, in our remedial attempts we should imitate, as nearly as we can, the processes of nature. The mixed contents of the small intestines furnish the natural stimulus of their peristaltic movements; and the excrement excites the larger bowels. When this natural stimulus is insufficient, the want may be supplied by some substance which is involved in the food, and accompanies it in its progress — as the bran of brown bread, already mentioned, or a few grains of rhubarb, or of aloes, swallowed immediately before dinner. In adjusting the proper quantity of the drug the patient must assist the physician. It should be just so much as suffices to effect what nature neglects to do, and no more. With some persons an aperient pill acts more comfortably and opportunely if taken at bedtime. Sometimes diarrhœa is associated with indigestion. This is usually connected with an excess of acid in the *primæ viæ*. The principle of treatment in such cases is obvious. Antacid and astringent remedies are proper; chalk, bismuth, catechu, kino, rhatany, logwood.

There are innumerable sympathies of distant parts with a dyspeptic stomach, in respect of which I can do little more than barely enumerate a few. Thus indigestion is often accompanied by pain in the head, with some confusion of thought: or at all events, with a loss of mental energy and alertness. Together with a violent headache there are frequently nausea and vomiting; and the complaint is popularly known by the name of the *sick-headache*; or, in the fashionable jargon of the day, as a *bilious* headache. I must refer you to a paper of Dr. Fothergill's in the sixth volume of the *Medical Observations and Inquiries* for a very good account of this troublesome complication.

I shall hereafter have a good deal to say respecting certain morbid conditions of the urine, which take their rise sometimes from faulty digestion in the stomach, sometimes from faulty assimilation of the digested aliment in the more advanced stages of the process of nutrition. These conditions of the urine, indicating grave derangements of the whole system, furnish the characters and the names of several distinct maladies.

I told you, in a former lecture, that certain affections of the viscera of the thorax are liable to be produced by mere indigestion. Palpitations of the heart, irregularities of the pulse, fits of asthma, are no uncommon accompaniments of a disordered stomach. This is partly to be ascribed to that reflex sympathy between the parts concerned, which I have so frequently mentioned; partly to the effect of flatulence, which, by resisting the descent of the diaphragm, impedes the free working of the lungs and of the heart. I told you, at the same time, that these symptoms torment many persons with the belief that they spring from organic disease. This notion is particularly apt to infest the minds of medical students. I suppose most teachers in our profession partake of that sort of experience of which Dr. James Gregory, of Edinburgh, used to speak in his lectures. He said that scarcely a winter passed over in which several of his pupils did not apply to him on account of palpitations supposed by them to depend upon structural disease of the heart: and in no single instance were their apprehensions well founded. They were all cases of mere dyspepsia and hypochondriasis.

Dyspepsia is often connected with phthisis, with leucorrhœa, with amenorrhœa and chlorosis: and some persons imagine that these diseases are *caused* by the dyspepsia. Indigestion may lead indirectly to the development of consumption, by producing debility; but the truer view of the matter seems to be that the dyspepsia is a consequence, rather than an exciting cause, of these complaints. When, for instance, leucorrhœa is cured by topical astringents, as it often may be, the indigestion frequently is cured too.

One of the worst occasional concomitants of dyspepsia is that peculiar state of the mind to which I just now alluded under the term *hypochondriasis*. This is, in truth, a species of insanity: but it is so often connected with disorder of the digestive organs, that Cullen, whose descriptions of disease are admirably clear and true, however faulty many of his theories may be, defines hypochondriasis to be "*Dyspepsia* —

cum languore, mæstitiâ, et metu, ex causis non æquis." In the following short paragraph, he completes the picture: "In certain persons there is a state of mind distinguished by the concurrence of the following circumstances. A languor, listlessness, or want of resolution and activity with respect to all undertakings: a disposition to seriousness, sadness, and timidity: as to all future events, an apprehension of the worst or most unhappy state of them: and therefore, often upon slight grounds, an apprehension of great evil. Such persons are particularly attentive to the state of their own health, to every the smallest change of feeling in their bodies: and from any unusual feeling, perhaps of the slightest kind, they apprehend great danger, and even death itself. In respect to all these feelings and apprehensions, there is commonly the most obstinate belief and persuasion."

Now when the attention of the hypochondriac is thus morbidly fixed upon the states and sensations of his digestive organs (as it is very apt to be) the patient becomes a plague to his physicians as well as to himself.

There are a few simple rules which ought always to be kept in mind in our *treatment* of dyspepsia; although we can seldom enforce them, as they ought to be enforced, upon our patients. What patients want, in general, is some medicine that will relieve them from their discomfort and uneasy feelings, and allow them, at the same time, to go on in the indulgence of those habits which have generated the discomfort. And such remedies have not yet been discovered.

One great and indispensable principle in the treatment of indigestion, is that of restricting the *quantity* of food taken at any one time. The gastric juice is probably secreted in a tolerably uniform quantity. The muscular contractions of the stomach must needs be impaired or impeded by such distension of that organ. For both these reasons the amount of food introduced into the stomach should be kept within the limits of its capacity and powers; and these limits are transgressed if an uneasy sense of fullness is produced by the meal. The great good which the late Mr. Abernethy unquestionably did to a host of dyspeptic patients, was owing much more, I am persuaded, to the rules of diet, and the restrictions as to quantity, which he laid down, than to his eternal blue pill.

Dr. Beaumont's observations led him to the conclusion that, within certain definite limits, the supply of the gastric menstruum was exactly regulated by the demand for it. So much aliment evoked so much gastric juice. But that the amount of the latter was never greater than the measure of the requirements of the frame: and therefore that whenever the food exceeded that measure, a portion of it remained undissolved, and even disturbed the due digestion of the rest.

Again, as Dr. Abercrombie has well remarked, and as Dr. Beaumont actually saw, various articles of food are soluble in the stomach with various degrees of readiness. Therefore, when the digestion is liable easily to be impaired, it is of great importance, not only to refrain from those substances which are known to be soluble with difficulty, but also to avoid mixing together in the stomach different substances which are of different degrees of solubility. Hence there are two reasons why it is salutary to dine off one dish. 1st, Because we avoid the injurious admixture just adverted to, and 2dly, because we escape that appetite and desire to eat too large a quantity, which is provoked by new and various flavours.

And another very important principle, greatly insisted on by Mr. Abernethy, is, that the stomach should have *time* to perform one task before another is imposed upon it. He always made his patients (at least he always strongly exhorted them) to interpose not less than six hours between one meal and another. Allowing from three to five hours for the digestion of a meal, and one hour over for the stomach to rest in, Mr. Abernethy's rule seems as much founded in reason as it is justified by experience. But we preach in vain on these topics. Mr. Abernethy was in the habit of saying that no person could be persuaded to pay due attention to his digestive organs, till death, or the dread of death, was staring him in the face. I have now in my mind a family consisting of a mother and three grown-up daughters, who are continually ailing and valetudinary. They profess to have great respect for my professional advice: yet I never can induce them to think that their plan of eating is a bad one. They are not early risers. They get to breakfast about half after ten or eleven. At two they think it absolutely necessary to eat luncheon, which consists of

a mutton chop or some hashed meat, with vegetables. At six they dine : and at eight they drink tea : and then they eat no more till the next breakfast. And this is just a picture of the habits of scores of families. They huddle all their food into the stomach, at four periods, within seven or eight hours ; and leave it idle for sixteen or seventeen.

Dyspeptic patients are very importunate to know *what* they may eat, and (more so still) *what* they may drink. It is of course impossible to lay down any general rules, which will suit every case. The stomach has its idiosyncrasies. I remember seeing a publication, some years ago, one section of which had this startling title, "Cases of Poisoning by a Mutton Chop." Dr. Prout knew a person who could not eat mutton in any form. He was thought to be whimsical, and mutton was frequently served up to him under some other guise, without his knowing it ; but it invariably caused violent vomiting and diarrhoea. Yet, for the average of stomachs, mutton is probably the most digestible of all meats. And for the average of stomachs some useful general directions may doubtless be given.

In fevers and inflammatory disorders, experience has taught us to forbid or to limit the use of flesh meat on account of its stimulating qualities. And when the stomach itself is affected with chronic inflammation, or with morbid sensibility, a diet restricted to farinaceous substances, and milk, is sometimes attended with the happiest consequences. I suspect that a false analogy has led some into the mistake of supposing that animal food ought to be refrained from, or taken in a scanty proportion, in merely dyspeptic complaints. Animal food is easier of digestion, in the human stomach, than vegetable food. A much smaller quantity of it is needed. It is not so likely to generate acidity. It is nearer, in its composition, to the textures into which it is to be incorporated by assimilation : or rather it contains precisely the same organic and inorganic substances as the body consists of. There is less of "conversion" requisite. Indeed we may look upon the appropriation of vegetable matter by granivorous and graminivorous animals, as one stage of the process by which such vegetable matter is prepared for the sustentation of carnivorous animals : even as one great end of vegetable life seems to be that of generating or concocting matter for the nutrition of the former class, out of inorganic materials, not fitted for that purpose. A more elaborate digesting apparatus is provided for the vegetable eaters. Man, indeed, is omnivorous. But his organs of digestion are more like those of the carnivorous than of the granivorous races. And it is notorious that vegetable food, when the stomach is weak, is followed by more flatulence, that is, is digested with more tardiness and difficulty, than animal food. Nevertheless, a mixture of the two, of well-roasted or boiled flesh or fowl, with a moderate portion of thoroughly-cooked vegetables, is better suited, in my opinion, for a feeble stomach, than a rigid adhesion to either kind of aliment singly. Water ; earthy and saline substances ; organic substances free from nitrogen, as starch, sugar, or oil ; organic substances containing nitrogen, as albumen, fibrin, or casein ; these all should be present in the daily food in such proportions as will suffice to repair the daily waste of the tissues, and the loss incidental to the process of respiration. After quantity, quality must be regarded. The more soluble in water, and the less irritating the food is, the more suitable is it for the functions of the stomach. All meats that have been hardened by culinary art, or by condiments, should be avoided by him, who, as the vulgar express it, has "a bad digester ;" all cured meats I mean — ham, tongue, sausages, and so forth. Mutton is thought to be more readily digestible than beef. Pork, its lean part at least, is much less so than either. All raw vegetables also must be eschewed ; salads, cucumbers, pickles. But if we press our prohibitions much more strictly than this, we incur the risk of fixing the patient's attention too curiously upon his diet, and upon the sensations of his stomach ; and of rendering him hypochondriacally alive to the miserable subject of his feeding.

Again, you will be continually asked whether you recommend malt liquor or wine, wine or brandy and water, white wine or port, sherry or madeira. Now it would be very easy to propound some positive rules in this matter, but it would not be so easy to vindicate them. Some allowance must be made, no doubt, for custom. I believe, however, that most dyspeptic persons would be better without any of these drinks. But it is very difficult to persuade them that the habitual use of strong liquors in small quantities can have any injurious effects. "It is not easy (says Cullen) to

engage men to break in upon established habits, or to renounce the pursuits of pleasure; and particularly to persuade men that those practices are truly hurtful, which they have often practised with seeming impunity." They are too ready to believe that it is unsafe to abandon their accustomed indulgence. A friend of mine, who visited, some years since, many of the American prisons, told me that the health of even the most inveterate spirit-drinker improves, instead of suffering, upon the sudden and total abstinence from spirits, which the regulations of those prisons enforce. There certainly are cases in which the digestion seems to be helped by a moderate quantity of wine, or beer, or spirits; yet no one can say before-hand—at least I cannot—which of them is to be preferred. Upon these points patients should interrogate their own sensations and experience, instead of seeking the oracular counsel of a physician. Drinks which are followed by evident disturbance and discomfort are manifestly unfit. And even when a favourable effect, for the time, appears to be produced, there is always a risk of ultimate detriment to the powers of the stomach from this habitual excitement.

There are states of mind, and habits of life, which, having no direct relation to the organs of digestion, yet exercise a material influence over their functions. Mental distress; mental solicitude; mental toil; over-much study; want of exercise: these are all prolific sources of dyspepsia. Sedentary habits, when their injurious effects are known, may be altered: excessive intellectual labour may be abandoned, or abridged; but it is seldom that we can minister to a wounded or an anxious spirit. Our task is hardest of all when the patient's anxiety relates to his own complaints; when he is morbidly engrossed by his bodily feelings, and despondent about his recovery. The management of the mind of a hypochondriac is peculiarly nice and difficult. It will not do to treat him as if his ailments were imaginary. He disbelieves you, contemns your judgment, and deserts you: to be fleeced perhaps by some villanous quack. You must hear what he has to say; show an interest in his case; and prescribe for him: assuring him that you understand his malady, that it is curable, and that he will be cured provided he follows your directions. If you can succeed in gaining his confidence, and in persuading him of this, the battle is half won. To tell such a person, however, not to think of his grievances would be worse than useless. The very effort to drive a subject from our thoughts fixes it there the more surely. But you must endeavour to turn his attention to other things; and to awaken in him some new interest. Prescribe *change*: change of air; change of place and scenery; change of society. Get him to *travel* in search of health; and the chances are in favour of his finding it. A tour, in fine weather, and through a pleasant country, combines almost all the ingredients which are, separately even, desirable: the withdrawal of the mind from its ordinary pursuits and cares; the diversion of the attention from one's self, by new and varied objects; exercise, carried on in the open air; a holiday from intellectual toil. Six weeks among the mountains of Switzerland, or upon the rivers of Germany, will often do more towards restoring a dyspeptic hypochondriac, than a twelvemonth's regimen and physicking at home.

With these disjointed hints, gentlemen, I must request you to be satisfied in respect to the principles upon which dyspepsia—and the hypochondriasis, which is in general so closely linked with dyspepsia—are to be managed. A full discussion of these subjects in detail would furnish matter for several lectures.

LECTURE LXXI.

Enteritis: its symptoms; causes; treatment. Mechanical occlusion of the Intestinal Tube. Colic. Colica Pictonum: its symptoms, complications, treatment, and prevention.

SOME of the diseased states of the intestinal canal, while they differ much in their essential nature, have yet many characters in common. Colic; ileus; enteritis; mechanical obstruction of the tube. It will be convenient, therefore, to consider these disorders in succession, and in some degree of connexion with each other.

In *colic* we have pain of the abdomen; pain of a twisting or wringing kind, occupying generally the umbilical region; vomiting; and costive bowels. Similar pains are apt to occur in diarrhoea; but they are transitory, and are then termed *gripings*, or more learnedly *tormina*. When they are violent, and more permanent, and, above all, when attended with constipation, they constitute colic.

You have not forgotten the symptoms of *peritonitis*. They are, briefly, pain in the abdomen, increased on pressure; and fever.

Now if, to the symptoms of colic, you add the symptoms of peritonitis, you have the symptoms of *enteritis*: by which word I desire to express the disease that is commonly called *inflammation of the bowels*. The term has lately been extended so as to signify any and every form of inflammation which any portion or tissue of the intestinal canal within the belly may suffer; but I use it in its old-fashioned sense. Cullen makes two species of enteritis. One of these consists in inflammation of the mucous membrane of the intestinal tube: he calls it enteritis *erythematica*. That is not the disorder I am about to speak of; but the other of his species, the enteritis *phlegmonodea*. I say that in colic we have abdominal pain, constipation, and vomiting. In peritonitis, the functions of the stomach and intestines are not, necessarily, affected: in enteritis they are. There is inflammation, not merely of the peritoneal coat, but of the areolar tissue uniting the several tunics, probably of the muscular tissue also, and often of the whole substance of the bowel at the inflamed part.

When the intestinal channel is any how closed up, and a bar placed to the passage of its contents, the symptoms of colic are very apt to ensue; and at length, the obstacle continuing, fatal inflammation is set up.

The term *ileus* is applied, I believe, to those cases, whether inflammatory or not, in which, by an inverted action of the intestines, their contents are carried in a retrograde course, into the stomach, and thence out of the body by vomiting.

Having made these explanations, I shall now address myself more especially to the consideration of enteritis.

It is of much practical importance to discriminate between enteritis and the disorders that resemble it; and particularly to distinguish it from colic. When it commences, as it sometimes does, with distinct rigors, and is attended by thirst, a hot skin, and a hard and frequent pulse, there is no room for doubt. But it often begins insidiously, with mere colicky symptoms; the pain, at first, is not much augmented, it may even be somewhat eased by steady pressure. If we mistake colic for enteritis, the error is of no great moment; but the opposite mistake, which is more common, may be fatal. Blood-letting, and the other remedies of enteritis, will not aggravate the mere colic; they may even, though unnecessary, relieve the patient. Some of the remedies of mere colic, are, however, highly dangerous when there is inflammation of the bowel. Physicians may fall into this error: patients, who choose to prescribe for themselves, commonly do so. They take stimulants, cordials, carminatives—the pleasantest and nearest at hand is a glass of brandy, or of gin. And in true colic these means are frequently of great service; but they exasperate the symptoms and increase the mischief when the disease is enteritis. Indeed, treatment of this kind will sometimes urge colic into enteritis. If the case be ambiguous, you must act upon the most unfavourable supposition, and treat the complaint as if you were sure that inflammation was present.

The pain of enteritis is increased by pressure. The pain of colic is not only not made worse, but it is actually mitigated often, by pressure; and it usually intermits entirely. I know that when there is simply flatulent distension of the intestines, pressure does sometimes increase the patient's uneasiness; but the uneasy sensation is very different from that acute suffering which shrinks from the touch in inflammation of their peritoneal covering. In enteritis there are also *paroxysms* of severe pain, determined, probably, by the peristaltic movements, or by the temporary distension, of the inflamed parts of the bowel; and the pain has frequently a twisting character; but there is not any thorough intermission. There is a duller abiding pain between the sharper fits. It is to be observed also, as a diagnostic circumstance, that the patient lies on his back, with his knees drawn up, as in peritonitis, and is fixed in that position, and for the very same reasons. If, in his agony, he toss about his arms, the trunk is kept motionless, and the respiration is thoracic: whereas in mere colic the mode of breathing is not altered, and the patient is apt to be turning and writhing in all postures, and out of one posture into another.

The nausea and vomiting are often most distressing. The patient not only rejects immediately whatever food, drink, or medicine he swallows, but he has fits of retching when the stomach is empty. In some instances, matters are cast up having the appearance, and something of the odour, of liquid fæces; or resembling, at any rate, the offensive fluids that are found in the small intestines after death in these cases. I may say that I have seen genuine excrement ejected, unequivocal ordure: and this may well happen if it be true that clysters, introduced into the rectum, have been voided through the mouth. Such a phenomenon would show that the whole tube was pervious; that there was no mechanical obstruction.

Although the fever, in the outset, may be high, and the pulse strong and hard, it soon becomes (as in all acute abdominal inflammations) small and wiry; or weak, and like a thread. In bad cases, as the disease proceeds, the abdomen begins to swell, becomes tympanitic; hiccup sometimes comes on; the pulse intermits or beats irregularly; the extremities grow cold; the features are sharpened and ghastly; cold sweats break out; the pain ceases perhaps; and the sphincters relax. The head is generally unaffected. Now and then delirium occurs late in the disease; but much more frequently the intellect remains clear to the very last. Death begins at the heart, and takes place in the way of asthenia.

You may probably have observed that the symptoms which I have been describing are just the symptoms which the surgeon so frequently encounters in cases of strangulated hernia. The symptoms of that surgical complaint are, in truth, most commonly at least, the symptoms of enteritis, caused by the forcible closure of the bowel. Obstruction to the passage of the contents of the gut gives rise to its inflammation. And we often find, after death preceded by the signs of enteritis, an internal mechanical obstruction—an internal strangulated hernia. In some cases, bands, or strings of coagulable lymph, the products of bygone inflammation, have formed snares (so to speak) for the gut, which at length they catch and constrict. They do no harm till some coil of intestine gets beneath or beyond them; and then they strangle it, as the phrase is. I have twice seen (as I think I formerly stated) the appendix vermiformis prove the immediate cause of fatal internal hernia. In one of these cases, the person had been a private patient of Dr. Macmichael's; and I went with him to examine the body. The free end of the appendix had become adherent to the mesocolon; and so a loop was made, through which a portion of the gut had passed. In the other instance, which I saw in Edinburgh, the appendix was literally tied round a piece of the intestine. Sometimes, again, there is intussusception: the upper part of the tube slips into the lower, fills it up, obstructs it; and inflammation fixes it there. Or it may be that a chronic thickening of the coats of the intestine has narrowed its channel; or a tumour presses upon the intestine from without; or some foreign substance, or morbid accumulation, plugs it up within; in all which cases a chronic disorder passes at length into acute inflammation. A very small hernia at one of the usual orifices—not large enough to manifest itself externally—is sometimes the cause of the obstruction; even though only a portion of one side of the gut may be nipped in the aperture.

Sometimes, but according to my experience less frequently, there is no mechanical impediment to account for the constipation. In all cases, whether there be mechani-

cal obstruction or not, the inflamed portion of the gut is of a red or dark colour; distended by its gaseous or liquid contents;

FIG. 109.

covered often, on its peritoneal surface with coagulable lymph; or adherent to the contiguous organs. When the gut is mechanically closed, the part which lies on this side the obstacle, as we follow the natural course of the channel, is inflamed; the part which lies beyond it is pale, contracted, and to all appearance, healthy. The line of demarcation is abrupt and strong; and it is determined by the obstacle. And the distinction between the healthy and inflamed portions is usually as sudden and decided, when there is no apparent obstacle. I mean that up to a certain spot the intestine is red like a cherry, or dark like a grape, large, and smeared (perhaps) with lymph or with pus; while immediately beyond that point and throughout the remainder of its course,

it is white, empty, and shrunk up into the semblance of a cord. The pathology of these last forms of the disease is full of difficulty. Some have held that the contracted

part was the original seat of disease, namely, of *spasm*; and that the upper adjoining portion of intestine became distended and inflamed in consequence of such spasm. Without attempting to explain these phenomena, which are comparatively unfrequent, I content myself with observing that it is the distended part which is the really inflamed part, and that its muscular coat appears to have lost its natural contractile power—not (I fancy) from over-stretching, as now and then happens to the urinary bladder—but from the effect of the inflammation.

The inflamed portion of bowel is often of a very dark colour, and even almost black, from that great congestion of blood in its tissues. Now this black colour has sometimes been erroneously set down as evidence of gangrene. You must not trust to the mere colour, however. If the coats of the bowel are firm, and if the peculiar odour of gangrene be wanting, you are not to conclude that mortification has taken place, simply from the dark appearance of the intestine.

FIG. 111.

Appearance of intestine in a case of inflamed colon; (a) false membrane composed of granule cells; (b) surface of a portion of colon beneath false membrane; (c) follicle or crypt containing cells similar to those composing the false membrane.—From *Habershon*.

Enteritis, not dependent upon any mechanical occlusion of the bowel, may arise under the operation of the ordinary causes of internal inflammation: cold and wet, for instance, applied externally, and especially to the feet and legs. Cold is thought to be particularly injurious in this way when the exposure happens soon after a meal: probably because at that time the digestive organs, being in activity, receive a more copious supply of blood.

The mechanical impediments that occur *within* the bowel, are still more various in kind than those which constrict it from *without*. Hardened fecal matters: intestinal concretions. Some of these are curious, and I shall hereafter have a word or two to say respecting their composition. Persons who are in the habit of taking a good deal of magnesia, or of chalk, to relieve acidity and heartburn, are liable to have these substances accumulate, and become indurated in the intestines. They generally begin to collect, I believe, around some accidental nucleus: and such a nucleus may very readily be supplied. A cherry-stone, a fish-bone, a gall-stone that has found its way into the bowel. Even a pill, prescribed to cure, may thus come to kill one's patient. Dr. Prout was asked to analyze certain odd-shaped, triangular bodies which had been voided at stool, and were supposed to be gall-stones, but he found that they were specimens of Plummer's pill, which had defied the solvent action of the gastric juice, and had passed into, and lingered in, the bowels. Unbruised mustard-seed, and carbonate of iron, are other remedial substances which, injudiciously administered, have collected in hard masses, and caused intestinal disease. It is seldom that we can discover, during life, what is the exact nature of the mechanical obstacle: but I have observed this peculiarity in most of the cases in which I have known it produced by *intussusception*, that after severe and sudden symptoms of obstruction and inflammation, *blood* has been passed by stool. Sometimes the included portion of bowel itself sloughs away, and is expelled *per anum*.

Inflammation of the bowels requires very much the same kind of treatment as peritonitis: indeed, the disease is in most cases peritonitis, and something more. The patient must strictly abstain from every sort of stimulus, and confine himself as much as possible to the horizontal position. He must lose blood also from the arm, and the earlier the better. The lancet is not to be withheld merely because the pulse is small. If the artery become fuller, and its beating more distinct, under venæsection—nay,

if the patient do not become faint—the first bleeding should be a free one. This is not only the safer plan, but in the long run it is the most economical of the blood and strength of the patient. As in simple peritonitis, the abdomen must be covered with leeches, and afterwards with fomentation cloths. Should one spot or region be more painful and tender than another, on that part the leeches are to be accumulated. It may be requisite to repeat the venæsection and the leeching once, or twice, or oftener; the propriety of such repetition depending upon the urgency and obstinacy of the symptoms, and upon the age and state of the patient. I am speaking of idiopathic enteritis, and of its earlier stages. In the advanced periods, when feebleness of the pulse is associated with tympany of the belly and coldness of the surface, it betokens weakness and sinking, and the tendency to death by asthenia; and, consequently, it then indicates support rather than depletion. So also when the enteritis is not idiopathic, but consecutive—when we have reason to believe that it arises out of a firm mechanical impediment—our employment of blood-letting must needs be modified by that circumstance.

One point in the management of enteritis, requiring great caution and judgment, relates to the exhibition of purgative medicines. The costive state of the bowels is apt to be looked upon as the main evil, and their evacuation as the chief indication of treatment; but great mischief, I apprehend, is likely to arise from the exclusive pursuit of that indication. I am still speaking of the idiopathic disease, where it is presumable that no mechanical obstacle exists to render the passage of the *faeces* impossible. Purgatives given by the mouth are often rejected by the stomach, with great distress to the patient. If they are retained, and fail to operate, they must do more harm than good. Certainly they should not precede the venæsection. I well remember, though it is now many years ago, being myself badly treated for enteritis. Being ill, in a strange place, I sent for the nearest practitioner, who happened to be a very ignorant man. Finding that I was sick, and that my bowels did not act, he gave me, for two or three days in succession, strong drastic purges, with no other effect than that of increasing my sickness and adding to the abdominal pain I suffered. I was then seen by a most intelligent physician (this was before I had paid any attention to physis myself), and the first thing he did was to have me copiously bled; and the immediate effect of that bleeding was to send me to the night-chair. And I am persuaded that when evacuations follow the administration of purgatives in such cases, they are often owing to the blood-letting and other antiphlogistic measures that are employed at the same time. These are the opinions of Dr. Abercrombie also, who says, “I confess my own impression distinctly to be, that the use of purgatives makes no part of the treatment of the early stages of enteritis; on the contrary, that they are rather likely to be hurtful until the inflammation has been subdued.” It is an instructive fact, that when purgative medicines *do* operate during the height of the inflammation, the stools they produce are merely watery; and it is only after the inflammation has been reduced, that *faeces* are discharged, and then in such quantity sometimes as to show that they must have been shut up in the bowels during the period of active inflammation.

You should wait, then, for the effect of other measures, blood-letting, leeching, fomentation, before you give active purgatives by the mouth; and in all stages of the disease, whatever laxatives are given should be of the mildest kind, such as are least likely to excite irritation of either the stomach or bowels.

The same objections do not apply to enemata, which soothe while they evacuate the lower parts of the canal. You will read or hear of great service done by an infusion of tobacco, or by the smoke of tobacco, thrown into the bowels through the rectum. Dr. Abercrombie speaks of a weak infusion of the leaves as being a remedy of very general utility. It should, I apprehend, be a *weak* infusion to be at all safe; but, of my own knowledge, I can tell you little or nothing about it. I do know, however, that the injection of a large quantity of merely warm water is often of much use: from two to six pints, for example, thrown up gradually and gently. Indurated *faeces* are softened and brought away in this manner, and the warm water acts as an internal fomentation, and is comforting.

Of internal medicines I believe the best you can give is a combination of calomel and opium, in such proportions as will restrain the purgative qualities of the calomel. The opium allays pain, and, perhaps, relaxes spasm; mercury tends to arrest the in-

flammatory action; and the more immediate effects of this combination are often found to be, a settling of the irritable stomach, a disposition to diaphoresis, and an improved pulse.

To sum up then, bleeding, and calomel and opium, are to be resorted to for checking the inflammation: and when that is in great measure abated (and probably not before) it will be right to give some mild laxative to clear out the bowels. There can be none more suitable or convenient than castor oil. But before we venture upon purgatives by the mouth, it will be proper to wash out the bowels by lavements of tepid water. These injections *may* sometimes have mechanically a beneficial effect upon the parts concerned in the inflammation: untwisting, for example, a twisted bowel; or setting free the half-incarcerated intestine. It is often expedient to administer them through a long tube passed as far as possible into the rectum.

There is one very important point in the treatment of enteritis that I have yet to mention. I have told you that in the advanced stage of the disease symptoms of sinking often come on: a total cessation of pain, failure of the vital powers, and coldness of the body. These symptoms, this collapse and approach to syncope, are generally considered to denote gangrene, and, therefore, a hopeless state of disease. Yet, in many cases which have proved fatal after similar symptoms, not a trace of gangrene has been discoverable. So that this unpromising change in the symptoms does not always indicate a morbid condition which is necessarily mortal. And if the patients are to be saved at all, they are to be saved by wine and support. We must combat the obvious tendency to death by asthenia.

"A man, aged forty, was affected with enteritis in the usual form, for which he was treated in the most judicious manner by a respectable practitioner. On the fifth day the pain ceased; the pulse was 140, and extremely feeble and irregular: his face was pale, the features were collapsed, and his whole body was covered with cold perspiration; his bowels had been moved. In this condition (says Dr. Abercrombie, from whom I quote the case) I saw him for the first time. Wine was then given him, at first in large quantities, and upon the whole, to the extent of from two to three bottles during the next twenty-four hours. On the following day his appearance was improved; his pulse 120, and regular; the wine was continued in diminished quantity. On the third day his pulse was 112, and of good strength, and in a few days more he was well."

Dr. Abercrombie relates other cases to the same effect; and most physicians, I suppose, have occasionally seen such. They teach us that we must not abandon our patients in despair, even under the most adverse circumstances. If diarrhœa should supervene with this state of collapse, opiates must be joined with the wine. External warmth is also a powerful auxiliary.

I know of no cases of disease more painful to witness or to treat than those which result from invincible obstruction of the intestinal tube. They are usually attended, at length, with enteritis; but they differ much in some respects from what I have called idiopathic enteritis. The inflammation is an accident or consequence of the obstruction; or of the means used to overcome it. They happen usually somewhat in this manner. A person thinks it expedient to take some aperient medicine. It has no effect. He repeats the dose. It causes pain and gripings, and probably sickness also; but still the bowels are not moved. Enemata are employed. They bring away, perhaps, some hardened fæces, but there is no further relief. Meanwhile the patient may have a clean tongue, a quiet pulse, a cool and soft skin, and a supple and painless abdomen. Purgatives of a more drastic kind are tried, but tried in vain; and the physician is summoned.

Now the first thing that you have to do, when called to a stubborn case of "obstruction of the bowels," is to search narrowly whether there be not some unsuspected external hernia. All delicacy must be waived; and every part of the body, where hernia may possibly show itself, must be submitted to inspection. If none be found, the rectum, and in women, the vagina, must be severally explored. Stricture, or a quarry of impacted fæces, may possibly be detected in the one: a uterine or other tumour, pressing upon the bowel, may perchance be felt through the other. I shall never forget the shock I once experienced on being sent for to see a woman, of middle age, who was *in articulo mortis*, and who, as I was told, had for some days been

labouring under sickness, pain in the abdomen, and constipation. In her left groin there was a large palpable strangulated hernia, which had not been detected by the practitioner in attendance, simply because it had not been looked for; and which was discovered only when it was too late. Once since, I had the better fortune to retrieve a similar oversight in time. Much pain in the abdomen there had been, and frequent sickness, and no alvine evacuation for eleven or twelve days. During this time active purgatives had been given, and had been worse than useless. The matter vomited became unequivocally stercoral. Within half an hour after the hernia was detected, the strangulated gut was released by an operation; and a life was saved which I firmly believe another day's delay would have forfeited.

Remember, then, that in every case of obstinate costiveness, with signs of inflammation within the abdomen, it is absolutely necessary, for your own credit and subsequent comfort, as well as for your patient's safety, to make diligent and thorough inquiry after such herniae as may be recognized externally.

But often you find nothing of the sort, and then you are at liberty to prosecute with more energy and decision the purgative plan of treatment. You prescribe strong doses of jalap and calomel; black draughts. The stomach being irritable, you give *pills* of cathartic extract, and repeat them at short intervals; or large doses of calomel, ten grains or a scruple, three or four times in succession. You inject stimulating clysters. Then you are driven to croton oil: and at last, in some vague hope of relaxing spasm, to opiates. If symptoms of inflammation spring up, you put fairly in force the remedies of inflammation; and especially blood-letting. But all is in vain. The medicines are vomited; or, if retained, they serve but to augment the patient's distress, producing or renewing the pain and the nausea. It is extraordinary how comfortable the patient sometimes becomes upon the intermission of these active attempts. Now and then he suffers tormina, or has fits of retching: but in the intervening periods his sensations and outward condition may be those of perfect health; only there is no alvine discharge.

Now, under these afflicting circumstances, the question will force itself upon you—how long am I to pursue the purgative system? Common sense, and common humanity, answer—you must stop it the instant you are convinced that there is a mechanical obstacle, which cannot be overcome. To persist in the use of drastic purgatives after that conviction, is to inflict wanton and needless torture upon the patient. But how are you to know this? That is one difficulty. And how are you, believing that it is so, to satisfy the patient's friends, that his disorder is irremediable; and to resist their importunity to try this and that: how persuade them to look passively on, while their relative is slowly perhaps, but surely, perishing? These are great and terrible difficulties.

You will be urged with all imaginable suggestions; even the most absurd. Crude mercury may perhaps be one. Pounds of this metal have been swallowed in such cases; in the hope, I suppose, that it would force a passage by its weight. But the obstacle may be in an ascending coil of intestine. And if not, experience does not teach us to put any faith in this rude mechanical remedy. It has often done mischief, and seldom or never done any good. The metal is apt to become oxidized in the body, and then to produce very distressing salivation. Yet in a case recorded by Mr. Adams, in which half a pound of quicksilver had been administered, two ounces and a half of the metal were voided, unchanged, five weeks afterwards. Profuse salivation is an evil which I have known to occur, and to trouble the patient greatly, some time after the ineffectual exhibition of large doses of calomel.

Dashing cold water over the abdomen and the lower extremities, is another rough expedient, which is sometimes successful in producing evacuations. It was adopted, after various other measures had failed, in the case in which the bowel was tied down by the adherent appendix vermiformis; and it caused the emptying of that part of the canal which lay beyond or below the internal hernia. It is plain that this partial success can be of little or no use; certainly of none that can compensate for the shock and annoyance of the cold affusion.

Let me not, however, be misunderstood. I do not say that you are to abandon all hope when purgatives (and, if need be, blood-letting) have failed, after a few trials to obtain evacuations from the bowels. Nor even that you are necessarily, for that reason, to give up the use of purgatives. The intestines may be torpid and insensible

to ordinary stimuli, and really require strong rousing. Dr. Abercrombie mentions the case of a gentleman whose bowels were locked up by an accumulation, as the result showed, of black hardened fæces. The obstruction, which had resisted the most powerful purgatives, and was accompanied by an evident and painful distension of a part of the abdomen, yielded at once to the repeated application of galvanism to that part: each application being immediately followed by a copious evacuation. Here the flagging muscular action was restored, apparently by the galvanic stimulus.

Two or three years ago I saw a similar case in consultation with Dr. Tyler Smith and Mr. Bryant. A gentleman of middle age presented the usual symptoms of intestinal obstruction. All the ordinary means of emptying the bowels were diligently tried, and tried in vain. Water was injected by means of a long tube passed through the rectum—with no better result. Almost in despair we at last had recourse to the electro-magnetic apparatus; and a current of the force thus generated was directed through the abdomen. You are aware that the strength of such a current is easily varied. When a low power was employed, the patient scarcely felt it. At a certain high power he suffered pain. But in a degree intermediate between these the sensations produced were agreeable. He said that he felt a “working” in his bowels; and in a short time they discharged their contents. This effect was repeated upon a repetition of the galvanic process: and our patient recovered perfectly. In this instance there was not much distension of the abdomen, and no rumbling movements of the intestines until they were excited by the electric current.

Another expedient which I have not yet mentioned is sometimes successful. This also I may as well describe to you by an instance. I was asked, one Sunday afternoon, by a physician, to see his little daughter, aged ten or eleven. On the preceding Tuesday she had gone to see the Queen open the Parliament, and was supposed to have caught cold there, for she began from that time to complain of pain in her belly. Some red discharge was reported by her nurse; and it was conjectured that this might be a show of commencing menstruation. However, she continued ill, and in pain, and was sick, and her bowels refused to act. On Saturday there was a discharge of blood and mucus. Dr. West was then consulted, who found no marks of menstruation. The discharges had been from the rectum. Purgatives, and ordinary injections, failed entirely of their purpose. It was pretty evident that the child was labouring under intussusception. As a last resource, and with a faint hope of rectifying the mischief, it was proposed to inflate the bowel with air. This was done, about midnight, by Mr. Erichsen, by means of the bellows used by the Royal Humane Society for producing artificial respiration. With my hand placed on the child's left flank, I could feel as well as hear the air enter with a rush and a noise upon each action of the bellows. Its entrance gave her some pain. She said, “There”—“that will do”—“oh don't,” &c. The inflation was continued for some minutes, yet the abdomen did not become much distended. After it was over the patient seemed easier; and in about two hours she passed a natural fecal stool. She got well without another bad symptom.

Occasionally relief is obtained by a sort of happy accident. Some time since, I attended an elderly lady, who from Wednesday morning to the next Monday noon, had had no alvine excretion, notwithstanding the employment of the most active cathartics. She suffered frequent paroxysms of pain and vomiting: but the abdomen was scarcely, if at all, distended; nor was it tender. At length she complained that what she vomited was stercoraceous—to use her own words, “what came upwards ought to have passed the other way.” It was a thin, brown-coloured, ill-smelling fluid. Dr. Mayo and Mr. Arnott were now associated with me in the case, and they touched and felt the abdomen as I had previously done. The lady observed that their hands were heavy; and she fancied that the pressure they made had displaced something within. And I believe that it was so: for before our consultation in the next room was over, word was brought us that the bowels had acted. She had passed a liquid motion precisely resembling the stuff she had last vomited. The next day, with one of several similar stools, a hard lump was voided, which proved to be a gall-stone, as big as a small walnut.

As large quantities of warm water had without difficulty been injected, I infer that the concretion had been impacted high up in the bowel, probably at the valve of the cæcum. Some years previously the lady had suffered severe abdominal pains, which at the time were ascribed to the passage of a biliary calculus through the gall-ducts.

In this instance again there was no evidence of any strong contractile efforts of the bowel above the place of obstruction.

Large enemata — as much as the intestines will patiently receive — gradually and gently introduced, and repeated three or four times a day, may sometimes succeed in breaking down and washing away masses of hardened excrement. And if these enemata are composed of milk or beef-tea, and are suffered to remain as long as they will, they may answer another important purpose; they may contribute sensibly to the nourishment of a patient who cannot retain food in his stomach. They are generally very soothing and comfortable, allaying tormina, and abating sickness; and they are adapted to every stage and variety of the complaint.

There are, however, cases in which we arrive at the melancholy but sure conviction that some mechanical impediment has rendered the bowel absolutely and hopelessly impassable. We fear this when, the constipation being obstinate, we discover a tumour, or hardness, in some part of the belly: or when we receive a history of some former inflammatory attack, since which the bowels have been habitually difficult to regulate. Our fears are strengthened when the patient feels that the injections reach a certain spot, and there always stop; and that the intestines rumble, and roll, and propel their contents downwards to the same spot, and no further. And this is the distinctive symptom upon which I desire to fix your attention. The abdomen gradually enlarges, especially if the patient be able to retain food. The intestines fill up above the obstacle; and then throes of pain occur, *spasms* the sufferers usually call them, attended with sickness; and during these pangs you may feel, and if the abdomen be uncovered you may see, immense coils of intestine, as big perhaps as one's arm, rise and roll over, like some huge snake, with loud roarings and flatulence. When this takes place, the time for giving purgatives is certainly over. The distended bowel requires no stimulus; it acts, and strives with all its power, but strives in vain, to overcome the opposing barrier. If you would consult your patient's ease, if you would not embitter and abbreviate his slender remnant of life, harass him no further with active remedies. In some cases violent inflammation quickly supervenes, and death arrives in a few days: in others, the patient survives, without any evacuation from his bowels, but with long intervals of ease and comfort, for four, or five, or six weeks. I had the pain of attending one lady who lived forty-six days after the last fecal alvine discharge. Even a brief respite may be of infinite value; giving time for the arrival of distant friends—for the settlement of worldly concerns—and for preparation of the spirit against the inevitable hour.

It is to these circumstances of irremediable disease that *opiates* are eminently adapted. Even when the symptoms are less desperate they are not without their use. I cannot better express what I think upon this point than in the words of the first Heberden, who says: "The probability of advantage from anodynes has determined me to recommend them; and experience has strongly confirmed this judgment. Under the protection of an opiate I have successfully given more and stronger purges than would have staid without its help. The patient's strength has been kept up by some refreshing sleeps: and even in hopeless cases, in which the dying person is harassed by unspeakable inquietude, he may be lulled into some composure; and without dying at all sooner, may be well enabled to die more easily. Lord Verulam blames physicians for not making the euthanasia a part of their studies: and surely, though the recovery of the patient be the grand aim of their profession, yet where that cannot be obtained, they should try to disarm death of some of its terror: and if they cannot make him quit his prey, and the life must be lost, they may still prevail to have it taken away in the most merciful manner."

I have spoken of these cases as being irremediable: but perhaps I have spoken somewhat too absolutely. Life may, sometimes, be relieved by a surgical operation. The gut may be punctured above the seat of obstruction, and suffered to discharge its contents through what is called an *artificial anus*. In a very interesting paper on this subject, in the thirty-fifth volume of the *Medico-Chirurgical Transactions*, Mr. Cæsar Hawkins states that at the time when he was writing, "four persons were living and in good health in this metropolis, whose lives had doubtless been prolonged by the operation." This expedient is feasible only when the obstacle is situated in the large intestine. Here only we ascertain, with anything like certainty, the exact place of the impediment. The colon may be pierced from behind, through

either loin, without injury to the peritoneum: this is the procedure known among surgeons as Amusat's. The same gut may be opened through the peritoneum, in either flank: this is Littre's operation. I am not qualified to pronounce a judgment upon the comparative merits of the two. The circumstances of each particular case would tend, I imagine, to determine which was the most eligible. An artificial outlet in the loin would probably be less disgusting to the patient, and less offensive to others, than in front of the body. Mr. Hawkins's statistics are not very encouraging. Of forty-four persons operated on, no more than one-half survived the performance of the operation. Among those who did recover, nine only lived so much as one year, and one only had then lived more than three years after it. A respite, however, of a year, or of a few weeks, may well be deemed a most precious respite. For my own part, in an appropriate case I should think it my duty to *mention*, though I should be slow to *recommend*, this *anceps remedium*. The risk of failure, and the penalty of success, should both be set fairly before the patient. The choice between inevitable death, on the one hand, and the chance of living for a short time with a very loathsome bodily infirmity, on the other, must be made by himself.

I should express much the same thoughts concerning that more daring exploit of surgery, which proposes to lay open and explore the cavity of the abdomen in the living subject, and to disentangle or set free the intestine, strangulated somehow, within. This procedure differs materially from the former, inasmuch as it contemplates no compromise between certain death, and complete recovery. It is fearful to be called upon for counsel, in seemingly desperate emergencies, respecting these scarcely less desperate remedies. Our doubts and indecision however, as in almost all questions of conduct, are the doubts and indecision of ignorance: ignorance, in the earlier periods, when the operation might be the more hopefully attempted, whether the obstacle be really insuperable by other means; ignorance whether, if so insuperable, it may be vincible by the help of the operation; ignorance, in short, as to its exact nature and place. These are predicaments in which the patient must be admitted to the consultation: and if the peril were my own, and all other prospect of relief had failed me, I would submit myself to this forlorn hope of rescue.
